These results suggest that the Cleveland criteria may not be particularly effective in differentiating those who can manage well with intensive outpatient treatment and those who require inpatient treatment for substance abuse. One reason for this may be that the criteria for inpatient treatment are overinclusive. Almost 75% of the patients in the intensive outpatient program met the requirements for inpatient treatment on one or more of the dimensions of the criteria as they were operationalized in this study. Making the criteria for inpatient treatment more restrictive might better differentiate patients who will not do well in outpatient modalities. However, simply requiring that patients meet criteria for inpatient care on more than one dimension did not result in much better identification of patients who did not do well in intensive outpatient treatment.

Several other explanations for these unexpected re-

sults should be considered. First, it is conceivable that the Cleveland criteria for inpatient care were not operationalized properly. While most of the dimensions are clearly spelled out by the authors, others are not as consistently clear as they might be. This was particularly true of dimension 3 (psychiatric complications) and dimension 6 (loss of control/relapse crisis). Although considerable care was taken to ensure that the criteria were represented accurately, it is possible that one or more dimensions were not operationalized in the manner intended by the authors of the Cleveland criteria.

Another possibility is that the Cleveland criteria do not apply to this population of male veterans of lower socioeconomic status with alcohol and cocaine problems. The Cleveland criteria, as currently written, may be more effective with other patient groups, such as middle-class, insured patients who are typically seen in private settings. Certain dimensions of the criteria may also be more or less valid with different groups of patients.

Finally, the Cleveland criteria for inpatient treatment are based on the assumption that patients with more severe symptoms require inpatient care because 1) day hospital or intensive outpatient environments do not have the requisite services to deal effectively with these problems, and 2) inpatient treatment has the appropriate services. However, our intensive day treatment program may have provided considerably more services than the typical intensive outpatient program envisioned by the authors of the Cleveland criteria. In fact, separate studies of this issue have shown that this day hospital program offers very similar types and amounts of treatment services in comparison with our 28-day inpatient program (A.I. Alterman and A.T. McLellan, unpublished manuscript). If the nature and amount of care provided in day hospital and inpatient programs are similar, then it is reasonable to expect the results that were obtained in this study.

In conclusion, determining the proper level of care for substance abusers remains a thorny problem. While a comprehensive system for assigning patients to proper treatment would certainly be welcome, more work appears to be needed as part of the process of "fine-tuning" and validating the Cleveland criteria. Moreover, even if criteria for inpatient rehabilitation of patients with substance abuse were successfully developed for one patient population, it is possible that they would have to be altered or adapted in order to be workable

with other patient populations. Therefore, additional studies with different patient populations and perhaps different types of inpatient and day treatment programs will be required to evaluate fully the Cleveland criteria and any other system for the assignment of patients to appropriate levels of care.

Mental Health Status and Community Adjustment After Treatment in a Residential Treatment Program for Homeless Veterans

Catherine Leda, M.S.N., M.P.H., and Robert Rosenheck, M.D.

***Objective:** An uncontrolled outcome study was conducted to examine clinical improvement and the relationship of psychiatric and substance abuse problems, community adjustment, and housing status among homeless veterans who participated in a multisite residential treatment program. **Method:** The study was performed at three U.S. Department of Veterans Affairs medical centers in Florida, Ohio, and California. Baseline, discharge, and 3-month postdischarge follow-up data were collected for 255 veterans admitted to the Domiciliary Care for Homeless Veterans Program. Multiple dimensions of outcome were examined, including psychiatric symptoms, alcohol abuse, drug abuse, social contacts, income, employment, and housing. **Results:** Program participation was found to be associated with improvement in all areas of mental health and community adjustment. Improvement in psychiatric symptoms was associated with superior housing outcomes and improvement in community adjustment. When correlates of improvement in alcohol and drug abuse were examined, only one of eight possible relationships was found to be significant: improvement in alcohol problems was positively associated with improvement in employment. **Conclusions:** Homeless mentally ill veterans derive clear benefits from participation in a multidimensional residential treatment program. Improvement in mental health problems, however, is weakly linked to improvement in other areas, suggesting that treatment programs may have to attend separately to multiple domains of life adjustment.*

(Am J Psychiatry 1992; 149:1219-1224)

During the 1980s the plight of the homeless mentally ill became an increasing focus of public attention and concern (1), a concern that was supported by a series of rigorously conducted community studies that demonstrated an exceptionally high prevalence of psychiatric and substance abuse disorders among the urban homeless (2-4). Although these studies did not provide a definitive explanation for the increased numbers and visibility of the homeless mentally ill across the country, most authorities agreed that the growth in urban poverty and the decline in the availability of affordable housing in most cities left people with psychiatric and substance abuse disorders at particularly high risk

for homelessness (5, 6). Psychiatric symptoms, substance abuse, social dysfunction, and lack of social supports were all identified as placing the mentally ill at special risk for homelessness (5, 6). Indeed, because of the presumed relationship between mental illness and vulnerability to homelessness, clinicians and program planners (1, 7) urged that specialized rehabilitation programs for the homeless mentally ill offer a combination of mental health services, housing assistance, and social rehabilitation services.

Scholarly attention has recently shifted from a primary focus on studying the psychiatric epidemiology of the homeless to evaluating approaches to their treatment (8). Although only a handful of outcome studies have been published (9-11), all have suggested that participation in specialized clinical programs can facilitate movement of the chronically mentally ill out of homelessness. Two premises about this population on which many of these clinical programs are based are that 1) mental illness, social dysfunction, and homelessness are related problems that exacerbate one another and 2) successful clinical intervention must target all of these problem areas. It follows that outcome studies of the homeless mentally ill should assess improvement in multiple domains.

^aEither housing was in imminent jeopardy or subject was institutionalized before admission but had no housing arrangements at the time of discharge.

^bSome veterans had more than one psychiatric diagnosis.

In this paper we examine the relationship of psychiatric and substance abuse problems, community adjustment, and housing status among homeless veterans who participated in a multisite study by the U.S. Department of Veterans Affairs (VA) Domiciliary Care for Homeless Veterans Program. The Domiciliary Care for Homeless Veterans Program is a multidimensional, time-limited residential treatment program for homeless veterans that addresses both personal and practical aspects of community adjustment (12, 13).

In this investigation we explored three hypotheses: 1) that severe psychiatric symptoms and substance abuse problems at admission would be associated with community adjustment problems and more prolonged homelessness, 2) that improvement in both mental health and community adjustment would be noted at follow-up, and 3) that improvement in psychiatric symptoms and substance abuse problems in particular would be associated with improvement in community

adjustment and housing status. We thus examined the impact of residential treatment and explored the relationship between mental health problems and community adjustment.

METHOD

In November 1987 the VA established the Domiciliary Care for Homeless Veterans Program at 20 VA medical centers. Each site has 25-75 beds and is staffed by a multidisciplinary professional team that provides seriously ill homeless veterans with medical and psychiatric treatment and with social-vocational rehabilitation services (12). All veterans with substance abuse problems are required to participate in substance abuse treatment, as well as group therapy and individual counseling. All sites offer prevocational and work-for-pay rehabilitation programs and maintain an active therapeutic community (13).

Of the 20 sites in the program, three were invited to participate in a descriptive outcome study: those located at the VA medical centers in Bay Pines, Fla., Cleveland, Ohio, and Palo Alto, Calif. These sites were selected because 1) they were among the first to have fully implemented programs, 2) they represent diverse regions of the country, and 3) they expressed interest in undertaking a demanding follow-up study. Although few objective operational data on the three sites are available, site visits indicated that one site emphasizes a cognitive-behavioral approach, another emphasizes vocational rehabilitation, and the third site stresses case management. Every first-time participant at each site during a 9-month period was invited to join the study. Of the 421 veterans so invited, 383 (91%) agreed to participate.

Data Collection

Data collection involved a three-step process. First, baseline data were obtained at the time of the veteran's first contact with the program and within 10 days of admission. Second, at the time of discharge, each veteran's primary clinician recorded pertinent data on the veteran's participation in the program. Finally, follow-up data on 255 subjects were collected through a structured interview with a research assistant 3 months after discharge. At one of the sites a few of the follow-up interviews were conducted by a clinician because the research assistant was not available. Because some veterans had relocated some distance from the VA medical centers after discharge, 70 (27.5%) of the veterans were interviewed over the telephone at follow-up, and the remaining 185 (72.5%) were interviewed in person.

Baseline data documented demographic and military service characteristics and the duration of the veteran's current episode of homelessness (time without a fixed, regular, and adequate nighttime residence). Duration of homelessness was evaluated with a six-level ordinal variable (see table 1). Psychiatric, alcohol, and drug prob-

lems were assessed by using selected items from the Addiction Severity Index (14), which were organized into composite indexes of alcohol problems, drug problems, and psychiatric problems by using the methods for combination suggested by McLellan et al. (unpublished manual of P.L. McGahan et al.), although slight modifications were made in the measure of psychiatric problems. The Addiction Severity Index has been shown to be reliable and valid in other studies (15), although tests of reliability and validity specific to this study were not performed.

The data collected at baseline also included measures of social contact, employment status, and current income. Frequency of social contact was expressed as a social contact index, a weighted sum of the frequency of face-to-face contacts with individuals that the veteran reported feeling close to in eight relationship categories. To calculate the social contact index, the number of close relationships was multiplied by the veteran's estimate of the frequency of contacts. Employment was measured on an ordinal scale, where 0 indicated the veteran did not work for pay at all during the 30 days before admission to the program, 1 represented working 1–19 days (part-time), and 2 represented working 20 or more days (full-time). Income was calculated by taking the sum of all reported sources of income in the 30 days before admission.

At discharge, length of stay and the mode of discharge from the program (successfully completed program, asked to leave for rule violation, left prematurely by choice, or other reason) were recorded. Postdischarge housing, employment, and health care arrangements were also recorded.

At the 3-month follow-up interview, measures equivalent to those used at baseline were completed. A detailed residential history was also taken; the veteran was asked to recall, for the 90 days after discharge, the number of nights spent in each of 11 types of living arrangements. These living arrangements were then collapsed to yield three categories: 1) number of nights housed, 2) number of nights institutionalized, and 3) number of nights homeless. Nights homeless was defined as the number of nights the veteran slept outdoors, in a shelter for the homeless, or in a vehicle. From these three categories a housing index was created. The housing index was a weighted sum; the number of nights housed was multiplied by 2, the number of nights institutionalized was multiplied by 1, and the number of nights homeless was multiplied by 0. This scoring system was based on the view that being domiciled in an apartment, room, or house was superior to being institutionalized and that both were superior to being homeless.

Subjects

Three months after discharge, 255 (66.6%) of the veterans in the cohort were located and interviewed, 58 (15.1%) were located but could not be interviewed, two (0.5%) were known to have died, and 68 (17.8%)

could not be located. The veterans reinterviewed 3 months after discharge were not significantly different from the veterans who were not interviewed in age, ethnicity, educational level, employment history, criminal history, duration of homelessness, most clinical diagnostic categories, mode of discharge from the program, and housing and employment status at discharge. However, there were significant differences between these groups in three admission variables and two discharge variables. At admission those who were reinterviewed were more likely to have never been married (36% versus 23%; $\chi^2=5.36$, $df=1$, $p=0.02$), more likely to have serious medical problems (67% versus 51%; $\chi^2=8.41$, $df=1$, $p=0.004$), and less likely to be clinically diagnosed with both psychiatric and substance abuse diagnoses (28% versus 41%; $\chi^2=6.22$, $df=1$, $p=0.01$). At discharge those who were reinterviewed were more likely to have been discharged to another institutional setting (23% versus 11%; $\chi^2=7.45$, $df=1$, $p=0.006$) and more likely to have had follow-up arrangements for health care treatment (90% versus 81%; $\chi^2=6.27$, $df=1$, $p=0.01$). Although only 66.6% of the cohort were reinterviewed, they appear to be a reasonably representative subgroup of the veterans who participated in the study.

The 255 veterans who were reinterviewed 3 months after discharge had a mean age of 40.1 years ($SD=9.6$), and 96.9% were male ($N=247$). The majority (56.9%) were white ($N=145$), 38.8% were black ($N=99$), 3.1% were Hispanic ($N=8$), and 1.2% were Native American or Asian ($N=3$). Only 2.4% were married ($N=6$); 62.0% were widowed, separated, or divorced ($N=158$), and 35.7% had never married ($N=91$). Almost 85% had completed at least 12 years of education ($N=213$), and in the 30 days before admission the majority (72.5%, $N=185$) had not worked at all. Eighty percent had been homeless for less than 12 months (table 1). The clinical psychiatric assessments conducted at admission by mental health clinicians indicated that 80.8% of the veterans met the criteria for an axis I *DSM-III-R* diagnosis of drug and/or alcohol abuse/dependency (table 1).

Analysis

Analyses were conducted in three stages. First, the Pearson product-moment correlation (r) was used to determine the correlation between mental health and community adjustment measures at admission. Next, t tests were used to determine the significance of differences between baseline and follow-up measures. Finally, improvement in clinical and community adjustment was determined by using standardized residual scores of the regression of follow-up scores on baseline scores. Pearson's r was then used to determine the correlation of improvement in mental health and community adjustment domains. All analyses were conducted for each site individually and for pooled data from all sites. The tables present pooled data and findings that were statistically significant at two or more sites ($p<0.05$).

^at test results were significant at two or more sites (p<0.05).^bNumber of close relationships multiplied by frequency of contacts.^cDays of paid employment in previous 30 days; 0=0 days, 1=1-19 days, 2=20 or more days.

RESULTS

The mean length of stay in the program for the interviewed veterans was 4.7 months (SD=3.2), and 38.4% were judged to have successfully completed the program (table 1). An additional 27.1% were asked to leave, primarily because of substance use, and 29.0% left against medical advice. At the time of discharge, more than one-half (52.5%) had housing arrangements, and 17.3% were discharged to other institutional settings (see table 1). Almost 40% had plans for employment after discharge.

Table 2 indicates the correlations of the baseline mental health indexes with duration of homelessness and baseline community adjustment. Only three of the 12 correlations were significant. The baseline index of psychiatric symptoms was negatively associated with employment, and the baseline indexes of alcohol and drug abuse were positively correlated with social contact, most likely reflecting the frequent contact of substance-abusing veterans with their "drinking and drugging buddies." Contrary to expectations, no associations were found between any of the baseline mental health indexes and the duration of homelessness or income. In this group psychiatric problems and substance abuse were not strongly associated with poorer community adjustment.

At admission 94.5% of the subjects (N=241) were literally homeless. In contrast, in the 90 days after discharge only 20.8% (N=53) were homeless for even 1 day and only 11.0% (N=28) reported being homeless

for more than 45 days. Furthermore, 83.5% (N=213) were housed for at least 1 day and 66.3% (N=169) reported being housed the majority of the time.

Changes in indexes of mental health and community adjustment are shown in table 3. All measures of mental health problems (psychiatric symptoms, alcohol problems, and drug problems) showed statistically significant reductions, and the most dramatic reduction from admission to follow-up was for psychiatric symptoms.

Significant improvement was also noted for all measures of community adjustment (table 3). Social contact increased, largely because a greater proportion of veterans were having daily contact with spouses or significant others, friends, health care providers, and other family members (data available on request). Monthly income rose substantially, by an average of \$470, primarily because of an increase in employment income, consistent with the significant improvement in employment.

Associations between measures of improvement in mental health problems and measures of improvement in community adjustment and housing are presented in table 4. Improvement in psychiatric symptoms was significantly but weakly associated with improvement in housing and with all three major measures of improvement in community adjustment.

When correlates of improvement in substance abuse were examined (table 4), only one significant relationship was observed: improvement in alcohol problems was positively associated with improvement in employment. No significant relationships were found between

improvement in drug problems and improvement in either community adjustment or housing status after discharge.

DISCUSSION

The central finding of this study of homeless mentally ill veterans was that participation in a residential treatment program was associated with improvement in both mental health and community adjustment. Although this was not a controlled outcome study, we believe that the degree of clinical improvement reported here would not have occurred in the absence of this intervention.

Other studies (12) have indicated that, among the homeless, individuals with psychiatric illnesses have more severe community adjustment problems than do others, but that trend did not emerge in our study. This finding suggests 1) that the psychiatric symptoms of a help-seeking clinical population are less severe than those of the general homeless population and 2) that within a chronically mentally ill population psychopathology and community adjustment vary with relative independence (16).

While previous studies have reported improvements in housing status associated with participation in specialized treatment programs for the homeless mentally ill (9-11), those studies have not shown improvement in other domains. To our knowledge this is the first outcome study on the treatment of the homeless mentally ill to indicate improvement in multiple areas, an important and positive finding in a population known to suffer from multiple problems.

Several methodological limitations, however, require comment. First, this study did not have an experimental design, and as a result the improvements noted cannot be conclusively attributed to treatment. Second, attrition at follow-up was substantial and may have biased the findings. Although few significant differences were found between the veterans who were interviewed at follow-up and the veterans who were not, the postdischarge outcomes of those not interviewed are unknown and may have been poor. Finally, the assessment of substance abuse was based on self-report data alone, which may have resulted in some underreporting. In spite of

these limitations, to our knowledge the findings reported here are the first to address multiple dimensions of outcome among the homeless mentally ill and are generally encouraging.

Although significant, the association between improvement in psychiatric symptoms and improvement in community adjustment was modest. Thus, these data only weakly support the hypothesis that treatment through the Domiciliary Care for Homeless Veterans Program effectively reduces psychiatric symptoms and thereby allows a veteran to resume productive social and vocational roles in the community. It must also be acknowledged that since psychiatric symptoms and community adjustment were measured at the same time, the direction of causality cannot be determined unambiguously. It is possible that social-vocational interventions in the Domiciliary Care for Homeless Veterans Program led first to improved community adjustment, which then resulted in reduced psychiatric symptoms. Most likely, the lines of influence, although weak, run both ways.

We found only one significant association between improvement in substance abuse and improvement in community adjustment. There are several possible explanations for this negative finding. First, improvement in community adjustment among veterans who evidenced improvement in substance abuse might have occurred slowly, and as a result, associations between these domains might not have been apparent only 3 months after discharge from residential treatment. Second, it is possible that some patients who remained dysfunctional because of continued substance abuse did not report the full extent of their substance use in the follow-up interviews.

Our hypothesis that improvement in psychiatric symptoms and substance abuse problems would be consistently associated with improvement in community adjustment and housing status was only weakly supported in this study. Clearly, additional studies are needed to more fully address these important questions. Such studies should, whenever possible, use experimental methods, validate substance abuse through objective means, and collect assessment data from as many domains as possible.

This study suggests a positive impact of participation in a residential treatment program for homeless veter-

ans on multiple clinical and community adjustment domains. It appears that, among the homeless mentally ill, improvement in mental health problems is weakly linked to improvement in other areas and that treatment programs may have to attend separately to multiple domains of life adjustment. The homeless mentally ill are among the least fortunate members of our society. They deserve our best efforts at both understanding and assisting them.

Sensitivity of Psychiatric Diagnosis Based on the Best Estimate Procedure

Therese A. Kosten, Ph.D., and Bruce J. Rounsaville, M.D.

Objective: A "best estimate" diagnosis is one made by expert clinicians on the basis of diagnostic information from direct interview conducted by another clinician plus information from medical records and from reports of family members. The authors address the question of whether the best estimate procedure can enhance the classification of psychiatric diagnoses of subjects who are interviewed directly. **Method:** Four hundred seventy-five subjects were interviewed directly: 201 opiate-addicted probands who sought treatment from a university-based clinic and 274 of their spouses and/or first-degree relatives. Subjects were interviewed by trained clinical assessors using the Schedule for Affective Disorders and Schizophrenia and classified according to Research Diagnostic Criteria. Two psychologists independently diagnosed the same subjects by applying the best estimate procedure. Lifetime rates of major and minor depressive disorder, antisocial personality, alcoholism, and drug abuse were calculated. The rates of diagnoses made on the basis of direct interviews alone were compared with the rates of diagnoses made according to the best estimate procedure. **Results:** Higher rates of diagnoses of all four disorders were made when the best estimate procedure was applied than when direct interview alone was used; the best estimate procedure also resulted in a minimal rate of false positives. **Conclusions:** The higher rate of diagnoses based on the best estimate procedure may represent an enhancement in the accuracy of psychiatric diagnoses or an increase in erroneous diagnoses. The authors consider the second possibility less likely.

(Am J Psychiatry 1992; 149:1225-1227)

Accurate classification of psychiatric diagnoses is important for genetic, epidemiologic, and treatment research. Misclassification can lead to erroneous conclusions about the etiology or outcome of psychiatric disorders. Using structured interviews and specific diagnostic criteria (1) provides a good basis for accurate classification of psychiatric diagnoses. However, direct interviews may not be available (e.g., in a family study when a relative cannot be contacted because of death, refusal, or other reasons). Moreover, the data from these interviews may be inaccurate if the subject withholds or provides false information.

To address these problems, psychiatric diagnoses can be obtained by enhancing interview data with informa-

tion from medical records and from reports of family members. Diagnostic information from all these sources are compiled and rated by expert clinicians to yield a "best estimate" diagnosis (2). These clinicians are not involved in the actual interviews of the subjects, including those of their family members. This blind procedure allows for objective evaluation of diagnoses but can lead to disagreements on diagnoses. When this occurs, the cases are reviewed and a consensus is reached. This process increases the cost of the study and raises the question of whether the best estimate procedure provides enough valuable diagnostic information to warrant its increased cost for subjects who are directly interviewed. For subjects who cannot be interviewed, the best estimate procedure has been shown to provide good diagnostic information (2).

The present paper addresses the question of whether the best estimate procedure can enhance the classification of psychiatric diagnoses for subjects who are interviewed directly. Working under the assumption that the best estimate procedure is more accurate than direct interview data because it is based on multiple sources of information, we compared psychiatric diagnoses obtained from direct interview only with diagnoses based on the best estimate procedure. We also assessed the degree to which the direct interview classified a subject

as having a psychiatric diagnosis when the best estimate procedure did not. The latter may represent either false positive direct interview diagnoses or erroneous classifications of best estimate diagnoses.

METHOD

The 475 subjects in this study were obtained from a large family study of opiate addiction (3). They included 201 opiate-addicted probands who sought treatment from a university-based clinic during the years 1983–1985 and 274 of their spouses and/or first-degree relatives, who were also interviewed directly. All subjects were at least 18 years old and gave informed consent in accordance with the Yale University Human Investigations Committee.

Subjects were interviewed by trained clinical assessors using the Schedule for Affective Disorders and Schizophrenia (SADS) (4) and classified according to Research Diagnostic Criteria (RDC) (5). Family history data were collected by using the family history version of the SADS/RDC. In the present paper, we report the lifetime rates (current or past) of major or minor depressive disorders, antisocial personality, alcoholism, and drug abuse.

Two psychologists independently diagnosed the same subjects by applying the best estimate procedure; they reviewed the data from direct interview, family history reports, and medical records. They discussed the diagnoses on which they disagreed and obtained a consensus on each. The interrater reliability was very good; mean kappa was 0.89 (range=0.62–1.00).

RESULTS

Data obtained from the direct interview were available for all 475 subjects diagnosed according to the best estimate procedure. Additional information from medical records was available for 128 (27%) of these subjects, and additional information from family history reports (i.e., interviews with family members about the subject) was available for 439 (92%) of these subjects. The mean number of family history reports from spouses and/or first degree relatives per subject was 2.2 (SD=2.2).

We calculated the percent of subjects who were given each of the diagnoses according to the best estimate procedure but who were classified as not having the diagnosis according to the direct interview data. These false negative rates are given in table 1. The rate of false negatives for all diagnoses ranged from 7% to 41%. The greatest false negative rate occurred for antisocial personality, and the lowest occurred for drug abuse.

We also calculated the percent of false positive diagnoses—subjects who were given the diagnosis by the direct interview method but not by the best estimate procedure. These data are also given in table 1. Overall, the false positive rates were minimal. Two disorders, alcoholism

TABLE 1. False Negative and False Positive Rates for Psychiatric Diagnoses Based on Direct Interview Only Compared With Diagnoses Based on Best Estimate Procedure

Diagnosis	Number of Subjects	False Negative Rates		Number of Subjects	False Positive Rates	
		N	%		N	%
Depressive disorders	275	57	21	200	3	2
Antisocial personality	194	80	41	281	4	1
Alcoholism	235	56	24	240	0	0
Drug abuse	326	23	7	149	0	0

and drug abuse, had no false positive rate. The other two diagnoses had minimal false positive rates.

We tested the generalizability of the enhanced accuracy of the best estimates with subsamples of the data. First, we compared the diagnoses of subjects for whom family history reports were available (N=439) with those for whom they were not available (N=36). There were no group differences in the false negative rates for the four diagnoses when the direct interview data were compared with the best estimate data (range=0%–5%).

Second, we compared those subjects whose medical records were available (N=128) with those whose records were not available (N=347). There were no group differences for the diagnoses of depressive disorders or drug abuse. However, when the direct interview diagnoses were compared with the best estimate diagnoses, the false negative rate for antisocial personality was 39% and the false negative rate for alcoholism was 33% for the 128 subjects with medical record data. These rates were significantly higher than the rates for the 347 subjects without medical records available, for whom the false negative rate for antisocial personality was 18% ($\chi^2=16.2$, $df=1$, $p<0.01$) and the false negative rate for alcoholism was 15% ($\chi^2=9.6$, $df=1$, $p<0.01$).

Finally, because almost half of the subjects were treatment-seeking opiate addicts, which may have artificially enhanced the agreement between direct interview and best estimate data, we compared the diagnostic agreement between the two procedures for the treatment-seeking probands (N=201) and their family members (N=274). We did not examine the group differences for the diagnosis of drug abuse because the proband group was defined by this diagnosis. There were no differences between the probands and their family members for depressive disorders and alcoholism. However, the false negative rate for antisocial personality was 48% for the probands, compared with 9% for their family members ($\chi^2=70.5$, $df=1$, $p<0.001$).

DISCUSSION

This study shows that when best estimate diagnoses, based on multiple information sources, are compared

with diagnoses made from direct interview only, there are many false negatives and few false positives. The false negative rate was particularly high for antisocial personality, but the rates for the depressive disorders and alcoholism were also high. Among the drug-abusing probands, the higher rate of diagnosis of antisocial personality when the best estimate procedure was applied was particularly striking. However, minimal or no false positives were obtained from the direct interview data compared with the best estimate data. These findings support the utility of making best estimate diagnoses for interviewed subjects.

We had expected that using the best estimate procedure would result in more diagnoses of disorders for which the criteria are based on information that subjects may tend to withhold (6). Our finding that the smallest increase was in the rate of drug abuse diagnoses was undoubtedly due to the fact that family members were aware that the probands were seeking drug abuse treatment. The higher rates of diagnoses of alcohol abuse and, particularly, of antisocial personality, are in line with the concept that interviewees may withhold information related to these disorders but this information can be gained by obtaining family history data and medical record data.

One finding that was particularly striking was the usefulness of including data from medical records in the best estimate diagnoses. The rates of diagnosis of two of the four disorders—alcoholism and antisocial personality—were significantly higher in subjects for whom medical record data were available than in subjects for whom these data were not available. Previous research also shows that medical record data enhance the rate of antisocial personality and alcoholism diagnoses as well as drug abuse diagnoses (7). The probable reason that we did not find this effect with the drug abuse diagnosis was that almost half of the subjects were treatment-seeking opiate addicts, which would make the medical record data somewhat obsolete.

Diagnoses based on family history information, compared with those based on direct interview, result in un-

derreporting of cases (8–10). We have now shown that the direct interview itself may result in underestimates of diagnostic rates. When family history information, along with medical record data, are incorporated into the diagnosis by using the best estimate procedure, the number of positive cases is greatly increased. This increase in diagnoses with the best estimate procedure may represent an enhancement in the accuracy of psychiatric diagnoses if, as we assumed, this procedure is a better standard, or it may reflect an increase in erroneous diagnoses because more errors may occur with greater available information. Although we consider the second possibility less likely, we have no other standard by which we can compare these diagnoses.

The Relationship Between Personality and *DSM-III* Axis I Disorders in the Population: Results From an Epidemiological Survey

Gerald Nestadt, M.B., B.Ch., M.P.H., Alan J. Romanoski, M.D., M.P.H., Jack F. Samuels, Ph.D., Marshal F. Folstein, M.D., and Paul R. McHugh, M.D.

Objective: The aim of this study was to assess the relationships between specific personality disorders and *DSM-III* axis I conditions in a community sample. **Method:** A total of 810 subjects were examined by psychiatrists in the second stage of the Eastern Baltimore Mental Health Survey, part of the Epidemiological Catchment Area Program of the National Institute of Mental Health. A semistructured examination, the Standardized Psychiatric Examination, was employed to assess axis I and axis II conditions. Scales for compulsive and antisocial personality disorders were derived from *DSM-III* criteria. The relationships between scores on these personality disorder scales and the presence of generalized anxiety disorder, alcohol use disorders (alcohol abuse and alcohol dependence), and simple phobia were evaluated by using logistic regression. **Results:** Higher compulsive personality scores were associated with a greater odds of generalized anxiety disorder and simple phobia but a smaller odds of alcohol use disorders. In contrast, higher antisocial personality scores were associated with a greater odds of alcohol use disorders but a smaller odds of generalized anxiety disorder. There was no relationship between antisocial personality scores and simple phobia. **Conclusions:** Personality disorders have specific relationships to axis I conditions, which suggests different vulnerabilities but also different protective influences.

(Am J Psychiatry 1992; 149:1228-1233)

D *SM-III* made a fundamental contribution to the study of personality disorders by providing explicit diagnostic criteria for these conditions and clearly distinguishing them from axis I psychiatric disorders (1). Since then, clinical interest in the personality disorders has burgeoned. It has become evident that the personality disorders are not discrete but show considerable overlap with each other (2). In addition, the question has been raised as to whether a categorical or dimensional approach to their characterization is more appropriate (3). More recently, the relationships between the personality disorders and axis I conditions have received considerable interest.

Despite this interest, there is remarkably little population-based data available to elucidate the relationships between axis II and axis I disorders. Most studies

to date have been limited to psychiatric inpatients and outpatients (4-8). Because patients may be selected on the basis of degree of emotional distress, health-seeking behavior, and types of psychiatric disorders, a spurious association between personality and other psychiatric disorders cannot be ruled out in studies based on clinical samples (9).

The objective of the present study was to determine if there are specific relationships between axis II and axis I disorders. We restricted our investigation to two *DSM-III* personality disorders—compulsive and antisocial personality disorders—and three *DSM-III* axis I disorders—generalized anxiety disorder, alcohol use disorders (alcohol abuse and alcohol dependence), and simple phobia. Subjects were selected from a survey of household residents and examined by psychiatrists using a semistructured method to diagnose *DSM-III* axis II and axis I disorders.

METHOD

Sampling

A two-stage population survey was conducted at The Johns Hopkins Medical Institutions in 1981 as part of the

Presented at the 143rd annual meeting of the American Psychiatric Association, New York, May 12-17, 1990. Received June 24, 1991; revision received Oct. 28, 1991; accepted Dec. 12, 1991. Epidemiological Catchment Area Program of the National Institute of Mental Health (NIMH). The survey population comprised household residents of eastern Baltimore, an area with approximately 175,000 adults living in about 93,000 households. After a probability sampling of households in the area, residents of the selected households who were between the ages of 18 and 64 years were randomly selected for interview. All older residents of these households were also selected (10).

The first stage of the survey involved a screening interview of 3,481 participants that was conducted by specially trained nonphysician surveyors. The interview instrument contained eight distinct screens for evidence of psychopathology, including elements from the NIMH Diagnostic Interview Schedule (11), the General Health Questionnaire (12), and the Mini-Mental State examination (13).

All subjects who were deemed "filter positive" for *DSM-III* psychiatric disorders (i.e., scored positive on one or more of the eight screens), and a 17% random sample from the entire group of 3,481 interviewees, were selected for the second stage of the survey, referred to as the clinical reappraisal. This was a diagnostic reevaluation of subjects who had previously been interviewed. A total of 1,086 subjects were selected for the clinical reappraisal, and 810 (75%) completed the examination. There were no obvious differences in demographic characteristics or scores on screening instruments between respondents and nonrespondents (14).

Clinical Reappraisal Examination

Each subject was examined by one of four board-certified or board-eligible psychiatrists who were graduates of The Johns Hopkins Residency Program. The psychiatrists remained completely blind to all information gathered during the first-stage interview. A comprehensive psychiatric interview employing a semistructured format, the Standardized Psychiatric Examination, was performed. This examination was designed to provide a thorough assessment of the subject's personal history, medical and psychiatric problems, and present mental state, as well as an evaluation of personality.

The Standardized Psychiatric Examination was developed specifically for this study. At the time of its development, no other instrument was available that could be used to record all information required to make most of the *DSM-III* diagnoses. The instrument included all 140 items of the ninth edition of the Present State Examination (15) and supplemented these with other items relevant to *DSM-III* nomenclature. This method emphasized current mental status, although information about past psychiatric history also was obtained. The four psychiatrists held regular conferences and tested themselves by means of videotapes of particular interviews so as to maintain high diagnostic consensus and interrater agreement. The reliability of the Standardized Psychiatric Examination has been described elsewhere (16).

Diagnosis and Scaling of Personality Disorders

When this study was designed in 1980, there were no diagnostic instruments for *DSM-III* personality disorders. We therefore employed an approach that, although not expressly developed for *DSM-III*, could be adapted for that purpose. This approach has been previously described (17).

In diagnosing *DSM-III* personality disorders, the examining psychiatrist tried to discern in the subject an enduring pattern of specific behaviors and reactions, as defined in the *DSM-III* manual. For the diagnosis of compulsive personality disorder, the psychiatrist discerned an enduring pattern of specific behaviors characterized by perfectionism, stubbornness, indecision, excessive work devotion, and emotional constriction. For the diagnosis of antisocial personality disorder, the psychiatrist sought an enduring pattern of specific antisocial behaviors, as defined in *DSM-III*.

Two methods were used to delineate traits for compulsive and antisocial personality disorders. In the inventory method, the examining psychiatrist was required to rate abiding characteristics on a 4-point scale ranging from 0 (absent) to 3 ("likely to result in distress under minor life stress") for compulsive personality and a 3-point scale for antisocial personality. These inventory decisions were based on judgments by the psychiatrist of historical information provided by the subject, as well as on the behavior of the subject that emerged spontaneously during the interview. As an integral part of the evaluation, the psychiatrist considered various aspects of the subject's past that illuminated adaptive responses. These aspects included parental relationships, sibling relationships, childhood adjustment and behaviors, schooling, occupational history, legal history, sexual history, marital history, and interests and leisure activities.

The second method required that the examiner ask a series of direct questions about particular traits and thereby reach a confirming or additional opinion on these character features. The scores for each of the five features of compulsivity were then summed in order to arrive at a compulsive personality score, and the scores of the 21 antisocial features were summed to arrive at an antisocial personality score. These scores ranged between 0 and 15 and between 0 and 42, respectively.

Final diagnoses of compulsive and antisocial personality disorders were generated by algorithms based on *DSM-III* criteria. Similarly, diagnoses of generalized anxiety disorder, simple phobia, and alcohol use disorders (alcohol abuse and alcohol dependence) were based on strict *DSM-III* criteria for symptoms and signs evident in the month before the examination. The internal construct validity of the personality disorder scales was evaluated by dichotomizing the ratings for each component trait into "absent" or "present" and computing intertrait tetrachoric correlations with a statistical program, LISCOMP (18). These correlations ranged from 0.33 to 0.68 for the five compulsive items and from 0.23 to 0.87 for the antisocial items. Most correlations were greater than 0.50.

FIGURE 1. Antisocial Personality Disorder Scores in a Community Sample of 810 Subjects, Weighted to the Population of Eastern Baltimore, 1981

Data Analysis

The distributions of personality scores were extrapolated to the general population of eastern Baltimore by weighting the cases according to sampling strata and response rates and adjusting to the 1980 census (10). Logistic regression analysis was employed to evaluate the associations between personality scores and axis I disorders (19). Age, gender, race, and filter status (i.e., whether the subject scored positive on any of the eight screens for psychiatric disorders) were controlled in these analyses. Filter status was controlled to ensure that any observed relationships between axis II and axis I disorders were not biased by the strategy for selecting subjects for the clinical reappraisal sample. The relative odds values obtained from these analyses estimate the increase in odds of the specific axis I disorder for each unit increase in score on the personality scale.

RESULTS

Distribution of Personality Scores

The distribution of compulsive personality scores in the population of eastern Baltimore has been reported previously (17). About 50% of the population had a score of 0 on this scale. Nearly 20% had a score of 1, and the remaining 30% had a score greater than 1. Persons meeting *DSM-III* criteria for the diagnosis of compulsive personality disorder (1.7% of the population) were at the upper extreme of the compulsive personality score distribution, with scores of 8 and above.

Figure 1 shows the distribution of antisocial personality scores in the clinical reappraisal sample, weighted to the population of eastern Baltimore. Nearly 66% of the population had a score of 0 on this scale. Approximately 20% had a score between 1 and 6, and the remaining 14% had a score greater than 6. Persons who met *DSM-III* criteria for the diagnosis of antisocial personality disorder (1.5% of the population) were at the

extreme of the antisocial scale distribution, with scores of 18 and above.

Personality and Axis I Disorders

The prevalence of *DSM-III* generalized anxiety disorder, alcohol use disorders, and simple phobia in subjects, as a function of scores on the compulsive and antisocial personality scales, were investigated. The prevalence of generalized anxiety disorder was strongly related to compulsive personality score; it ranged from 0.7% for those with a score of 0 to over 9% for those with a score of 3 and above (χ^2 for trend=20.5, $df=1$, $p<0.001$). When age, sex, race, and filter status were controlled in a logistic regression model, the odds of having generalized anxiety disorder increased by 50% for every unit increase in compulsive personality score (estimated relative odds=1.54, 95% confidence limits=1.3–1.8, $p<0.001$).

The prevalence of simple phobia also was related to compulsive personality score, ranging from 15% for those with a score of 0 to 27% for those with a score of 3 and above (χ^2 for trend=10.2, $df=1$, $p=0.001$). From logistic regression analysis, the odds of *DSM-III* simple phobia increased with compulsive personality score (relative odds=1.1, 95% confidence limits=1.02–1.2, $p=0.02$).

In contrast, there was an inverse relationship between the prevalence of alcohol use disorders and compulsive personality score (χ^2 for trend=3.3, $df=1$, $p=0.07$). From logistic regression analysis, the odds of alcohol use disorders declined as compulsive personality score increased (estimated relative odds=0.9, 95% confidence limits=0.7–1.1, $p=0.27$).

A different pattern emerged for the relationships between the three *DSM-III* axis I disorders and antisocial personality score. There was no relationship in the prevalence of generalized anxiety disorder as a function of antisocial personality score (χ^2 for trend=0.2, $df=1$, $p=0.66$). From logistic regression analysis, there was an inverse relationship between the odds of generalized anxiety disorder and antisocial personality score that did not reach statistical significance (estimated relative odds=0.9, 95% confidence limits=0.7–1.1, $p=0.24$).

There was no relationship between the prevalence of simple phobia and antisocial personality score (χ^2 for trend=0.01, $df=1$, $p=0.92$). The odds of simple phobia did not change with antisocial personality score (estimated relative odds=1.0, 95% confidence limits=0.98–1.1, $p=0.30$).

In contrast, the prevalence of alcohol use disorders increased in a dose-response fashion with antisocial personality score, ranging from 4% in those with a score of 0 to 22% in those with a score of 3 and above (χ^2 for trend=42.7, $df=1$, $p<0.001$). From logistic regression analysis, the odds of alcohol use disorders increased 10% for each unit increase in antisocial personality score (estimated relative odds=1.1, 95% confidence limits=1.03–1.13, $p<0.001$). These results

did not change appreciably after removal of the alcohol use item from the antisocial personality scale.

Dose-response relationships are illustrated in figure 2, which shows the probabilities, predicted from logistic models, of generalized anxiety disorder as a function of compulsive personality disorder score and of alcohol use disorders as a function of antisocial personality disorder score.

DISCUSSION

We employed a dimensional perspective to investigate specific relationships between compulsive and antisocial personality features and three axis I disorders in a population-based sample of household residents in eastern Baltimore. Psychiatric diagnoses were made by psychiatrists using a semistructured, standardized instrument. The personality scales were found to have acceptable internal construct validity. The distributions of compulsive and antisocial personality scores in the population demonstrate the arbitrary nature of cutoff values for the definition of *DSM-III* compulsive and antisocial personality disorders and support the use of the dimensional, scaled approach for these personality features.

Controlling for age, sex, race, and filter status in logistic regression models, we found that increasing scores on the compulsive personality scale were associated with a significantly greater odds of generalized anxiety disorder and simple phobia and a smaller odds of alcohol use disorders. In contrast, increasing scores on the antisocial personality scale were associated with a smaller odds of generalized anxiety disorder and a significantly greater odds of alcohol use disorders but showed no relationship with simple phobia. There did not appear to be distinct thresholds for these relationships.

Our findings are generally consistent with clinical studies showing a relationship between compulsive personality and anxiety disorders (20, 21). For example, Alnæs and Torgersen (4) found that simple phobia was more than twice as prevalent in outpatients with compulsive personality disorder as in outpatients with other personality disorders. Gasperini et al. (22) found compulsive personality disorder in 15% of 46 outpatients with generalized anxiety disorder, compared to 4% of nonpatient control subjects (our calculations: $p=0.06$, Fisher's exact test). Our findings are also consistent with clinical and population-based studies showing a strong relationship between antisocial personality and alcohol use disorders (23–25). Our findings of an inverse relationship between compulsive personality and alcohol use disorders and between antisocial personality and generalized anxiety disorder await further investigation in community samples.

Conclusions drawn from this study must be tempered by several methodological limitations. First, additional informants were not available for validating personality attributes reported by the subjects (26). This might be particularly problematic in the case of

FIGURE 2. Predicted Probabilities of Generalized Anxiety Disorder and Alcohol Use Disorders, by Compulsive and Antisocial Personality Disorder Scores in a Community Sample of 810 Subjects in Eastern Baltimore, 1981

ratings of antisocial personality, which relied heavily on subjects' reports of past behaviors. Second, given that assessment of mental status occurred at a single point in time, it may have been difficult to discriminate stable personality features from symptoms (27). However, the examining psychiatrist attempted to elicit enduring personality features over the subject's entire life span. Clarification of the relationships between axis I and axis II disorders will be enhanced by the employment of prospective designs and additional validated scales and dimensions, with assessments of state and trait made by researchers who are blind to each other's assessments (17).

Our finding of specific relationships between dimensionally scaled personality disorders and axis I disorders have important theoretical and clinical implications. These relationships are analogous to those involving intelligence (28). Parallels between this construct and that of personality measured on dimensions can be useful.

Mental retardation is described in terms of categories in *DSM-III* and other nomenclatures. These categories reflect scores on a dimension, intelligence, that is assessed by specific tests. It is found that an individual's probability of developing difficulties correlates nega-

tively with his or her score on a measured intelligence scale. However, the distress of the intellectually limited individual may be evident only under adverse circumstances or in the face of increasing burdens; it is in these situations that his or her vulnerabilities emerge. The actual precipitant for evoking distress is usually specific, i.e., being faced with a situation that taxes problem-solving abilities. Emotional responses may include anxiety, demoralization, and depression.

A variety of personality dimensions have been proposed (29–32). As with intelligence, individuals on the extremes of these dimensions are vulnerable to develop specific problems. For example, in clinical settings, anxiety is common in introverted, quiet, or compulsive individuals, whereas depression is often found in borderline individuals (33). Misbehavior such as alcoholism, drug use, and self-injury occurs more often in extroverted and sociopathic individuals (34).

These mental states or behaviors emerge when the individual is faced with adverse situations or increased burdens. The emotional reactions and behaviors of the individual can be construed as the consequence of a potential defined by aspects of the individual's personality, as well as by provocations exerted by environmental circumstances. This formulation has been described as the "neurotic paradigm" (28).

The adversity may be specific to the vulnerability, such as failure at work for the compulsive individual or inability to fulfill personal goals for the antisocial person. In our view, the threshold for emergence of distress and demoralization in a person confronted with adversity is influenced by the individual's position on the underlying continuum of the personality dimension, as well as by the nature of the specific adversity. This threshold also may be affected by other personal attributes (for example, intelligence, educational attainment, other personality characteristics), the presence of social supports, and previous experience in managing difficult situations.

The nature of personality remains elusive, and ultimate criteria for the validation of personality features await clarification. Nevertheless, as demonstrated in the present investigation, the measurement of personality dimensions has clinical relevance. By helping to identify individuals with specific vulnerabilities, reliable dimensional assessments of personality may point the way toward specific strategies for the treatment and prevention of psychiatric disorders.

Posttraumatic Adaptation and Distress Among Adult Burn Survivors

Robert P. Roca, M.D., M.P.H., Robert J. Spence, M.D.,
and Andrew M. Munster, M.D.

Objective: The purpose of this study was to examine the prevalence, natural history, and psychosocial impact of posttraumatic symptoms in adult burn survivors. **Method:** Forty-three adult inpatients at a regional burn center were assessed at discharge with standardized instruments to determine the presence of psychiatric disorder, assess personality, and quantify depression. Thirty-one patients were evaluated 4 months after discharge. **Results:** Posttraumatic stress disorder was diagnosed in 7% of patients at discharge and in over 22% of patients at follow-up. Symptoms of avoidance and emotional numbing (DSM-III-R criterion C symptoms) tended to emerge after discharge from the hospital. While posttraumatic symptoms were associated with symptoms of depression, they were not strongly associated with psychosocial adjustment to illness; psychosocial adjustment was more strongly related to aspects of personality, the injury itself, and its treatment. **Conclusions:** Since adult burn survivors often develop new symptoms of posttraumatic distress after leaving the hospital, longitudinal surveillance is required to detect new cases and provide appropriate treatment. Survivors at risk for poor psychosocial adjustment after discharge may be identifiable during hospitalization, and preventive treatment strategies should be developed and tested for this population.

(Am J Psychiatry 1992; 149:1234-1238)

Burn injury—a painful, frightening, and extraordinary trauma—may precipitate posttraumatic symptoms in at least some burn survivors. In a study predating DSM-III, Andreasen and Norris (1) described transient “phobic” and “traumatic” neuroses in many burn survivors. More recently, Courtemanche and Robinow (2) published two illustrative case reports of DSM-III posttraumatic stress disorder (PTSD) in burn victims, and Patterson et al. (3) found that 29% of hospitalized burn survivors met criteria for DSM-III PTSD at some point before discharge.

While these papers illustrate the importance of screening burn patients for posttraumatic distress, they leave unanswered many questions about the prevalence, natural history, and functional implications of

PTSD in this population. One significant unsettled question is the time course of posttraumatic symptoms. Patterson et al. (3) found persistent PTSD (at telephone follow-up 40 days after discharge) in only one of 11 burn survivors who had met criteria for PTSD in the hospital, which suggests that posttraumatic symptoms may be short-lived in this population. However, since Patterson et al. did not perform follow-up interviews of patients who had *not* had PTSD in the hospital, the true prevalence of PTSD at follow-up could not be stated. It is entirely possible that PTSD might have emerged after discharge in patients who had had few, or even *no*, posttraumatic symptoms in the hospital.

Equally uncertain is the relationship between posttraumatic distress and postburn psychosocial adjustment to illness. While it is plausible that PTSD symptoms could hinder postburn psychosocial rehabilitation, this has not been demonstrated among burn patients diagnosed by DSM-III-R criteria, and one study of World War II prisoners of war suggests that even severe symptoms of PTSD are compatible with considerable preservation of psychosocial functioning (4). Furthermore, there is evidence that postburn disability may be related to a variety of clinical variables (e.g., aspects of the burn or its treatment, the patient's personality or premorbid psychopathology) that are independent of the emergence of PTSD symptoms (1, 5).

Presented in part at the 143rd annual meeting of the American Psychiatric Association, New York, May 12-17, 1990. Received Aug. 1, 1991; revision received Dec. 10, 1991; accepted Jan. 17, 1992. From the Departments of Psychiatry and Surgery, The Johns Hopkins University School of Medicine; The Francis Scott Key Medical Center; and the Baltimore Regional Burn Center, Baltimore, Md. The purposes of this study were to describe the prevalence, clinical phenomenology, and clinical correlates of PTSD and its component symptoms among adult burn survivors and to examine the relationship of these symptoms to postburn psychosocial adjustment.

METHOD

Subjects for this study were drawn from the 20-bed inpatient unit of a regional burn center located in an urban medical center. Patients were routinely screened for delirium and other psychiatric disorders soon after admission and followed clinically until discharge. Adult patients who were hospitalized for over 48 hours, who were approaching discharge, and who were not persistently delirious or otherwise inaccessible to interview were invited to participate in the study. Participating subjects took a battery of tests including the Structured Clinical Interview for DSM-III-R (SCID) (6), the Beck Depression Inventory (7), the NEO Personality Inventory (8), and the Millon Clinical Multiaxial Inventory—II (9).

An attempt was made to reinterview the subjects 4 months after discharge. The SCID was readministered over the telephone to subjects who could be reached only in that manner. In addition, a research assistant mailed to all located subjects a packet containing the Beck Depression Inventory and the Psychosocial Adjustment to Illness Survey (10, 11), a standard questionnaire designed to measure post-illness functioning in seven domains: health care orientation, vocational environment, domestic environment, sexual relationships, extended family relationships, social environment, and psychological distress.

Student's *t* test was used to compare group means, and Pearson correlation coefficients were calculated to evaluate the relationships between continuous variables. Relationships between dichotomous variables were evaluated with the chi-square test.

RESULTS

During the study period, 134 adults were admitted to the unit. Of these, 68 could not be given the formal test battery because of death (*N*=14), discharge within 48 hours (*N*=41), persistent delirium (*N*=10), severe attention deficit disorder (*N*=1), or nondelirious psychotic states (*N*=2). Of those able to participate (*N*=66), 43 gave consent and completed the diagnostic interview.

Efforts were made to contact all study patients 4 months after discharge. Twenty-nine (67.4%) were contacted and agreed to retake the SCID; in addition, two patients who had not been tested at discharge entered the study and were given the SCID. Seventeen patients completed and returned the Psychosocial Adjustment to Illness Survey and the Beck Depression Inventory. Those who completed the SCID at follow-up were compared to the 14 who did not; no significant differences were found between these groups in age,

sex, level of education, total body surface area burned, length of stay, or type of burn.

Thirty-five patients (81.4%) in the study were men, and 30 (69.8%) were white. Their average age was 34.7 years (*SD*=11.8). Twelve (27.9%) had a SCID lifetime diagnosis of major depression, while 16 (37.2%) and 10 (23.3%) had lifetime diagnoses of alcohol and marijuana abuse or dependence, respectively. Length of hospital stay averaged 21.6 days (*SD*=21.9). Twelve (27.9%) had burns involving at least 25% of total body surface area, and 23 (53.5%) had facial involvement. Thirty-one (72.1%) had flame or flash burns, while the remaining 12 (27.9%) had chemical, electrical, or scald injuries.

PTSD

At the time of discharge, only three patients (7.1%) met all *DSM-III-R* criteria for PTSD, including the 1-month duration criterion. An additional three patients met all criteria for PTSD *except* for the 1-month duration criterion.

At 4-month follow-up, of the three patients who had met full criteria for PTSD at discharge, one still had PTSD and one was completely symptom free. The other was lost to follow-up. Of the three who had met all criteria except the 1-month duration criterion, one had PTSD at 4 months and one met criteria B (i.e., reexperiencing symptoms) and D (i.e., increased arousal); the other was lost to follow-up. Overall, then, of the four most symptomatic patients who were available for follow-up, three had significant symptoms 4 months after discharge.

Of the 31 patients who took the SCID at 4-month follow-up, seven (22.6%) met full criteria for PTSD. One of these had met full PTSD criteria and one had met all but the 1-month duration criterion at discharge. The remaining five were new cases.

Individual Symptoms of Posttraumatic Distress

Individual symptoms of posttraumatic distress were more common than the fully expressed syndrome of PTSD at discharge and remained common at 4-month follow-up, sometimes emerging in persons who had lacked these symptoms at discharge.

Reexperiencing symptoms. Twenty-five of 43 patients (58.1%) had at least one reexperiencing symptom (i.e., met PTSD criterion B) at discharge (table 1). Of these 25, 19 were available for follow-up at 4 months, and 14 continued to report a reexperiencing symptom at that time.

Of the 31 patients who took the SCID at 4-month follow-up, 19 (61.3%) reported a reexperiencing symptom at that time. In four of these cases, the symptoms had *not* been present at discharge; in one case, the symptomatic status at discharge was not known. Thus, in only four cases were reexperiencing symptoms present at follow-up in patients who had not had such symptoms at hospital discharge.

TABLE 1. Reexperiencing of PTSD Symptoms (DSM-III-R Criterion B) by Adult Burn Survivors at Discharge and 4-Month Follow-Up

PTSD Symptoms	Discharge (N=43)		4-Month Follow-Up (N=31)	
	N	%	N	%
Intrusive memories	16	37.2	14	45.2
Recurrent dreams	11	25.6	10	32.3
Flashbacks	6	14.0	6	19.4
Intense distress at similar events	13	30.2	11	35.5
Any ^a	25	58.1	19	61.3

^aMet criterion B.**TABLE 2. Symptoms of Avoidance and Emotional Numbing (DSM-III-R Criterion C) in Adult Burn Survivors at Discharge and 4-Month Follow-Up**

PTSD Symptoms	Discharge (N=43)		4-Month Follow-Up (N=31)	
	N	%	N	%
Avoidance of thoughts related to event	17	39.5	12	38.7
Avoidance of activities related to event	9	20.9	13	41.9
Inability to recall aspects of event	4	9.3	6	19.4
Diminished interest in usual activities	6	14.0	6	19.4
Feelings of estrangement from others	7	16.3	2	6.5
Restricted range of affect	4	9.3	2	6.5
Sense of foreshortened future	11	25.6	11	35.5
At least three symptoms ^a	8	18.6	8	25.8

^aMet criterion C.

Symptoms of avoidance and emotional numbing. Eight of 43 patients (18.6%) had three or more symptoms of avoidance or emotional numbing (i.e., met PTSD criterion C) at the time of discharge (table 2). Of these eight, five were available for 4-month follow-up, and two of these still met criterion C.

Of the 31 patients who took the SCID at 4-month follow-up, eight (25.8%) met criterion C at that time. Of these eight, six had not met this criterion at discharge. Thus, the majority of patients who reported significant symptoms of avoidance/numbing at 4-month follow-up had developed these symptoms after discharge from the hospital.

Symptoms of increased arousal. Thirteen of 43 patients (30.2%) had at least two symptoms of increased arousal (i.e., met PTSD criterion D) at discharge (table 3). Of these 13, 10 were available for follow-up, and six still met criterion D.

Of the 31 patients who took the SCID at 4-month follow-up, 14 (45.2%) met criterion D at that time. Of these 14, eight had not met this criterion at discharge. Thus, many patients reporting significant symptoms of increased arousal at 4-month follow-up had developed these symptoms after discharge.

TABLE 3. Symptoms of Increased Arousal (DSM-III-R Criterion D) in Adult Burn Survivors at Discharge and 4-Month Follow-Up

PTSD Symptoms	Discharge (N=43)		4-Month Follow-Up (N=31)	
	N	%	N	%

At least two symptoms ^a	13	30.2	14	45.2

^aMet criterion D.

Posttraumatic Distress and Mood, Burn Type, and Personality

Mood. At discharge, Beck Depression Inventory scores were significantly higher among patients who met criterion C (i.e., avoidance/numbing) (scores of 15.0 versus 7.9; $t=-2.18$, $df=36$, $p=0.04$) and criterion D (i.e., increased arousal) (scores of 14.7 versus 7.0; $t=-3.01$, $df=36$, $p=0.005$) than among other patients. There were no significant relationships between reexperiencing symptoms and Beck Depression Inventory scores.

Patients with PTSD at 4-month follow-up were marginally more depressed than other patients (Beck Depression Inventory scores of 15.0 versus 8.2; $t=-1.72$, $df=13$, $p=0.11$). Two PTSD patients met criteria for major depression and one met criteria for dysthymia at the time of follow-up.

Burn type. Twenty-one (67.7%) of 31 patients suffering flame or flash burns had a reexperiencing (criterion B) symptom at discharge; in contrast, four (33.0%) of 12 patients who had sustained other types of burns (e.g., chemical, electrical) reported such symptoms. This difference was marginally significant ($\chi^2=2.9$, with Yates's correction, $df=1$, $p=0.09$). There were no relationships between type of burn and other posttraumatic symptoms.

Personality. Of the patients who took the NEO Personality Inventory at discharge, those who met criterion B at discharge (N=9) scored lower on the inventory domain of openness than those who did not have such symptoms (N=17) (scores of 46.4 versus 53.0; $t=2.33$, $df=24$, $p=0.03$), and those who met criterion C (i.e., avoidance/numbing) (N=3) scored lower on the inventory domain of extraversion than those who did not (N=23) (scores of 46.7 versus 59.8; $t=3.86$, $df=24$, $p=0.001$). In addition, those who met criterion D (i.e., increased arousal) (N=6) scored higher on the inventory domain of neuroticism than those who did not (N=20) (scores of 58.5 versus 48.5; $t=-2.93$, $df=24$, $p=0.007$).

Of the patients who completed the Millon Clinical Multiaxial Inventory—II at discharge, those who met criterion C (i.e., avoidance/numbing) (N=4) were more schizoid than those who did not (N=30) (scores of 26.5

versus 17.0; $t=-2.85$, $df=32$, $p=0.008$). They were also more avoidant (scores of 35.3 versus 14.6; $t=-3.10$, $df=32$, $p=0.004$), schizotypal (scores of 32.5 versus 14.5; $t=-2.76$, $df=32$, $p=0.01$), and borderline (scores of 38.3 versus 18.5; $t=-2.55$, $df=32$, $p=0.02$). Those who met criterion D (i.e., increased arousal) ($N=10$) scored higher on the borderline scale (scores of 30.8 versus 16.7; $t=-2.58$, $df=32$, $p=0.02$) than those who did not ($N=24$).

Intoxication Upon Admission and Posttraumatic Distress

Blood and urine toxicology screens were ordered at the time of admission for 35 of the 43 patients. Six (17.1%) were positive for alcohol, five (14.3%) for cannabis, three (8.6%) for cocaine, and one (2.9%) for a noncocaine stimulant. Thirteen (37.1%) were negative, and seven (20%) were positive for nicotine, caffeine, and/or therapeutic drugs.

Five (83.3%) of the six patients with detectable blood alcohol levels at admission met criterion D (i.e., increased arousal) at discharge; in contrast, only six (20.7%) of the 29 other patients (including those with detectable levels of other drugs) did so ($\chi^2=6.38$, with Yates's correction, $df=1$, $p=0.01$). Patients with detectable blood alcohol levels were not significantly more likely than other patients to meet criterion B (i.e., reexperiencing symptoms) or C (i.e., avoidance/numbing). There was no relationship between posttraumatic distress and intoxication with any other substance at the time of admission, and there was no relationship between intoxication with any substance, including alcohol, at the time of admission and posttraumatic symptoms at 4-month follow-up.

Other Variables

The likelihood of reporting posttraumatic distress (i.e., meeting criteria B, C, and D or having PTSD) at discharge was not significantly influenced by age, sex, length of hospital stay, total body surface area burned, presence or absence of facial involvement, or the experience of delirium during the hospitalization.

Predictors of Posttraumatic Distress at 4 Months

A number of variables were examined to determine whether clinical features observable at discharge predicted the presence of posttraumatic distress at 4-month follow-up. Patients who had a reexperiencing (criterion B) symptom at follow-up had reported lower openness on the NEO Personality Inventory at discharge (scores of 45.0 versus 51.9; $t=2.27$, $df=19$, $p=0.04$) than other patients. Patients who met criterion C at follow-up had scored lower on the narcissism scale of the Millon inventory—II at discharge (scores of 31.2 versus 40.0; $t=2.06$, $df=25$, $p=0.05$) than other patients. There were no other significant relationships between personality (assessed at discharge) and posttraumatic symptoms reported at 4-month follow-up. There were

also no significant relationships between posttraumatic symptoms at follow-up and other clinical data obtained during the hospitalization, including demographic variables, type of burn, length of stay, presence or absence of delirium, and alcohol intoxication at the time of admission.

Correlates of Postburn Adjustment

There were no significant relationships between postburn adjustment, as measured by the Psychosocial Adjustment to Illness Survey at 4-month follow-up, and the likelihood of having PTSD or of meeting criterion B, C, or D. In contrast, there were significant relationships between scores on the survey at 4-month follow-up and aspects of the injury itself, the treatment provided, and the personality of the victim. The greater the extent of facial involvement, the poorer the adaptation in the survey's social ($r=0.68$, $N=17$, $p<0.01$) and sexual ($r=0.65$, $N=17$, $p<0.01$) domains. Social impairment was also correlated with the extent of sex organ injury ($r=0.67$, $N=17$, $p<0.01$). Those who were delirious during the hospitalization had poorer vocational adjustment (scores of 10.0 versus 3.78; $t=-2.90$, $df=13$, $p=0.01$) and poorer domestic adjustment (scores of 9.2 versus 4.3; $t=-2.16$, $df=13$, $p=0.05$) at follow-up than those who were not delirious. In addition, length of hospital stay was significantly correlated with problems in the vocational ($r=0.73$, $N=17$, $p<0.001$) and domestic ($r=0.67$, $N=17$, $p<0.01$) environments at follow-up.

Patients with Millon Clinical Multiaxial Inventory—II features of the histrionic, antisocial, passive-aggressive, and/or borderline personality types at discharge were particularly likely to show poor adaptation at 4 months. Impairment in domestic adjustment correlated with antisocial ($r=0.71$, $N=14$, $p<0.01$), passive-aggressive ($r=0.64$, $N=14$, $p<0.01$), and borderline ($r=0.74$, $N=14$, $p<0.01$) features. Problems in relationships with extended family members were related to histrionic ($r=0.64$, $N=14$, $p<0.01$), antisocial ($r=0.67$, $N=14$, $p<0.01$), and passive-aggressive ($r=0.68$, $N=14$, $p<0.01$) traits. Global maladjustment (total Psychosocial Adjustment to Illness Survey score) at 4 months was most strongly correlated with Millon Clinical Multiaxial Inventory—II antisocial ($r=0.74$, $N=14$, $p<0.01$) and borderline ($r=0.69$, $N=14$, $p<0.01$) qualities.

There were no significant relationships between dimensions of personality as measured by the NEO Personality Inventory and postburn adjustment as measured by the Psychosocial Adjustment to Illness Survey.

DISCUSSION

To our knowledge, this is the first study to use standardized instruments and *DSM-III-R* criteria in a prospective, longitudinal examination of PTSD and psychosocial adaptation to illness among burn survivors. The main finding was that posttraumatic symptoms

were very common both at discharge and at 4-month follow-up. The full PTSD syndrome tripled in prevalence between the time of discharge and 4-month follow-up, reflecting the delayed emergence of symptoms of avoidance and emotional withdrawal. Impairments in postburn psychosocial adjustment were less strongly related to symptoms of posttraumatic distress than to aspects of the injury itself and the personality of the survivor. As anticipated, substance abuse, especially alcoholism, was highly prevalent in this population (12), and the prevalence of depression was similar to that found among hospitalized patients in general (13).

The differential time course of PTSD symptoms—the tendency for reexperiencing symptoms (criterion B) to be present in the hospital and for symptoms of avoidance and emotional numbing (criterion C) to emerge after discharge—was an unanticipated finding that might be explained by hospitalization itself. Intrusive thoughts and similar symptoms can readily be experienced by hospitalized patients. On the other hand, fulfillment of criterion C requires the manifestation of avoidance behaviors and the experience of altered emotional reactivity to everyday stimuli. Hospitalized patients have limited opportunities to manifest these symptoms and generally must be discharged before they can judge their ability to face stimuli reminiscent of the burn and to resume interpersonal relationships. Thus, the delayed emergence of criterion C symptoms may reflect delayed exposure to opportunities to experience pertinent symptoms.

While some individuals with PTSD undoubtedly suffer severe functional incapacity, the present data show surprisingly little relationship between symptoms of posttraumatic distress and impairments in postburn psychosocial adaptation. While this finding was unexpected, it is consistent with other studies which show that PTSD is compatible with remarkable functional recovery (4). Since the present data did suggest higher levels of depression among patients with PTSD symptoms, it is possible that a study involving more subjects (to minimize the probability of type II error), longer follow-up, and/or the use of other measures of psychosocial adaptation (e.g., return-to-work records) might show stronger links between psychosocial impairment and PTSD symptoms. For now, however, it is accurate to say that symptoms of PTSD may occur in patients who acknowledge little or no psychosocial disability on a self-report instrument.

The best predictors of impaired postburn psychosocial adaptation were aspects of the injury itself, the treatment course, and the personality of the survivor. Burns involving the face and the sexual organs were associated with postburn impairments in the social and/or sexual domains. Patients who were delirious in the hospital and who had longer hospital stays had poorer adjustment in the domestic and vocational domains. Patients with prominent passive-aggressive, antisocial, and borderline personality features had difficulties in

several domains of postburn adjustment, perhaps reflecting long-standing and preexisting difficulties, especially in interpersonal relationships.

These findings have implications for both clinical care and future research. The delayed emergence of posttraumatic symptoms in many patients suggests the need for longitudinal surveillance of all burn survivors to allow for detection of new symptoms and provision of appropriate treatment. The relationships between postburn psychosocial adaptation and aspects of the injury, its treatment, and the personality of the patient suggest the potential for early identification of burn survivors at high risk for poor adjustment and for the development and evaluation of preventive educational and psychotherapeutic (14) treatment strategies for burn survivors with these high-risk characteristics. The absence of strong relationships between posttraumatic symptoms and postburn psychosocial adjustment was surprising and may have resulted, at least in part, from the small size of the follow-up cohort. To further clarify the functional implications of posttraumatic symptoms in this population, longitudinal studies involving larger numbers of subjects and longer follow-up intervals should be undertaken.

Pubertal Stage and Panic Attack History in Sixth- and Seventh-Grade Girls

Chris Hayward, M.D., M.P.H., Joel D. Killen, Ph.D.,
Lawrence D. Hammer, M.D., Iris F. Litt, M.D., Darrell M. Wilson, M.D.,
Beverly Simmonds, M.A., and C. Barr Taylor, M.D.

Objective: Although the incidence of first panic attacks appears to peak during adolescence, little is known about which features of adolescence contribute to the risk of a first panic episode. The purpose of this study was to compare the relative importance of age and pubertal stage in explaining the occurrence of panic attacks in adolescents. **Method:** From a school-based sample of sixth- and seventh-grade girls, 754 subjects completed both a structured clinical interview determining history of one or more panic episodes and a self-assessment of Tanner stages of pubertal development. A multiple logistic regression analysis was performed with panic attack history as the dependent variable and pubertal stage, age, and their interaction as the independent variables. **Results:** A history of one or more four-symptom panic attacks was found in 5.3% of the girls (N=40). After age was controlled for, pubertal stage was significantly related to panic attack history. At each age, higher rates of panic attacks were found in the more physically mature girls. **Conclusions:** Pubertal stage, after adjustment for the effects of age, appears to predict panic attack occurrence in young adolescent girls. Understanding the link between puberty and panic may offer clues regarding the onset and etiology of panic attacks.

(Am J Psychiatry 1992; 149:1239-1243)

Early identification of panic disorder is important because of the associated risk for developing agoraphobia and depression (1, 2) and because of the association between panic disorder and mortality from suicide (3) and possibly cardiovascular disease (4, 5). Early onset of an anxiety disorder may also increase the risk for drug abuse in young adults (6). There are effective treatments for panic symptoms, raising the possibility that panic-related morbidity is preventable. The first symptom of panic disorder is the initial panic attack. Not every person who experiences a panic attack will

develop panic disorder. Approximately 10% of the adults in the Epidemiologic Catchment Area (ECA) study reported ever having had a panic attack, whereas the lifetime prevalence for panic disorder in the same study was 1.6% (7). Recognizing risk periods for the beginning stages of panic disorder would facilitate primary and secondary prevention efforts.

Both panic attacks and panic disorder are thought to be uncommon in children (8, 9). There are case reports of panic disorder in children (10-14), but a population-based survey of 792 children 11 years old detected no cases of panic disorder (15). Adolescence, on the other hand, appears to be a period of increased reports of panic symptoms. In the ECA study, for adults with simple panic attacks the peak age at onset was during adolescence (16). In case series from child and adolescent psychiatry clinics (17-21), most patients seen for panic symptoms are adolescents. Although epidemiologic studies indicate that panic disorder is still uncommon during adolescence (22), less frequent panic attacks may not be. In a small pilot study (23), we previously reported a lifetime prevalence of isolated four-symptom panic attacks of 11.6% among 95 ninth-grade students. There may be an increase in the frequency of panic attacks between childhood and adolescence that, to date, has received little systematic evaluation or explanation.

Presented at the 143rd annual meeting of the American Psychiatric Association, New York, May 12-17, 1990. Received April 17, 1991; revision received Dec. 10, 1991; accepted Jan. 17, 1992. This possibility that panic symptoms may be more common in adolescents than in children focused our attention on adolescence as a risk period for the occurrence of panic attacks. We wondered whether puberty represents a specific risk factor separate from that of age. While puberty and the associated hormonal changes have been linked to the onset of various psychological symptoms (24), to our knowledge a specific association with panic attacks has not been reported in any population-based study of adolescents, nor do we know of any report of the relative influence of age and puberty. Thus, the purpose of this study was to fill this gap in knowledge by investigating the relationship of pubertal level versus age to history of panic attacks in a representative sample of adolescent girls at various stages of sexual maturation.

METHOD

Subjects

The subject group in this study was a school-based sample of peripubertal girls who were participating in a health curriculum intervention study (J.D. Killen et al., unpublished manuscript). All sixth- and seventh-grade girls enrolled in four middle schools located in two school districts in northern California were eligible to participate in this study. The parents of 19 subjects requested that their children not be involved in the study, leaving 939 eligible to participate. The age range of these students was 10.3–15.6 years. The school districts serve a suburban, ethnically diverse population near a large metropolitan area. This study was undertaken with the approval of our institution's committee for protection of human subjects and involved a passive consent process that afforded the student the opportunity to decline to participate. To maintain confidentiality, each student was assigned an identification number that was used to track all data collected. All assessments were performed at the schools during class periods on 5 consecutive school days.

The general subject variables collected by questionnaire included age, birth date, current grade, and ethnicity.

Structured Interviews

Previous population-based research concerning panic attacks in adolescents (25, 26) has used questionnaires to determine panic attack status. Although sensitive, questionnaires for panic attacks may lack specificity, yielding high false positive rates (27). To avoid this possibility, we determined the history of panic attacks with a structured diagnostic interview similar to that used in our previous work (23).

The Structured Clinical Interview for DSM-III-R—Nonpatient Version (SCID-NP) (28) was used to diagnose panic attacks. Although this instrument has not been standardized in this age group, our previous expe-

rience of using the SCID with adolescents led us to believe that the subjects would comprehend the questions and participate in the interview. Panic attacks attributable to social or simple phobic stimuli were not coded as panic attacks. Medical conditions and stimulants known to precipitate panic attacks were not assessed.

The interviews were performed by 10 trained graduate students in psychology. The training consisted of two 4-hour training sessions, during which the criteria for panic attacks were reviewed and videotaped SCID interviews of patients with panic disorder were observed. The subjects were interviewed in private settings during class periods and were informed that all information was confidential. The two circumstances under which breach of confidentiality was allowed were suicide risk and child abuse. Confidentiality was broken during the structured interview in two cases of suicidality. These cases were uncovered incidentally, as we did not formally ask about suicidal thoughts or intentions.

For estimation of interrater reliability, two interviewers were present during 40 of the interviews. One interviewer performed the interview, and both interviewers rated the subject independently. The kappa coefficients for the interview questions ranged from 0.66 to 1.00. The kappa coefficient for the designation of panic attack versus no panic attack was 0.79. We also compared the proportions of students identified by the 10 interviewers as having had a panic attack, and there was no statistical difference between the proportions.

Tanner Staging

Pubertal development was assessed by self-staging with the method of Duke et al. (29). The students were presented with standardized line drawings and written descriptions of the five stages of breast development and the five stages of pubic hair development (30). The subjects were instructed to select the drawings that best reflected their pubertal levels. While self-rating is not as accurate as physician-determined Tanner stage, previous research in which self-ratings were independently verified by pediatricians indicates that adolescent self-ratings correlate highly with physician-determined stage of pubertal development. For example, in one study of 43 girls aged 9 to 17 (29), self-ratings based on photographs agreed with pediatrician examination ratings in 37 of the 43 cases ($\kappa=0.81$) for breast stage and in 40 of the 43 cases ($\kappa=0.91$) for pubic hair stage. In a study of 66 girls aged 7 to 12 years (30), self-ratings based on drawings were compared with pediatrician examinations, and the kappa for the older girls, who would be closer in age to the girls in the present study, was 0.73. These findings indicate that girls in this age group can accurately self-assess Tanner stage.

Since Tanner breast stage and Tanner pubic stage were highly correlated in this sample ($r_s=0.66$, $p\leq 0.0001$), Tanner stages are reported as a summary measure to avoid collinearity in regression analyses. The Sexual Maturity Index was used as the summary measure of

Tanner stages (31). The Sexual Maturity Index is the mean (rounded up to the next integer) of the two Tanner stages, breast and pubic hair.

Statistical Analysis

The data were analyzed by using the Statistical Analysis System for the personal computer (32). Two-tailed statistical tests were used to compare groups. Each subject was assigned to one of two groups: 1) those who had experienced at least one four-symptom panic attack in their lifetimes and 2) those not reporting a four-symptom panic attack. Group differences in age were compared by using the Student's *t* test. Ethnic groups were collapsed to include only the ethnic groups that constituted at least 10% of the sample, and the remaining groups were included in the designation of "other." Group differences in ethnicity were compared with a chi-square test statistic.

Multiple logistic regression analysis was performed with panic history as the dependent variable and age, Sexual Maturity Index, and the interaction of age and Sexual Maturity Index as the independent variables. A 5% two-tailed level of significance was used. For significant effects, the adjusted odds ratios with 95% confidence intervals are presented.

RESULTS

Of the 939 eligible subjects, complete interview data were obtained for 823 subjects (87.6%). The 116 for whom we did not obtain complete interview data were absent during the days the assessments were conducted, were present during the days in which the interviews were performed but were not interviewed owing to time constraints involved with conducting interviews during class periods, or did not finish the panic section of the interview. There were no significant differences in age and ethnicity between those completing the interview and the remainder of the sample.

Of the 823 subjects with complete interview data, 754 (91.6%) completed the Tanner staging evaluation. Those who did not complete the Tanner self-rating were either absent on the day it was performed or were unable to comprehend the instructions. There were significant differences in mean age and ethnicity between the 754 subjects who completed the Tanner self-staging and the remainder of the sample. The noncompleters were older, and more of them were Hispanic.

Of the 754 subjects who completed both the interview and the Tanner self-staging, 40 subjects (5.3%) reported having experienced at least one four-symptom panic attack in their lifetimes. An additional four subjects (0.5%) reported having at least one limited-symptom panic attack. There were no significant differences in mean age or ethnicity between those with and those without panic attack histories. Their mean ages were 12.3 (SD=0.8) and 12.4 (SD=0.7) years, respectively. The ethnic distribution of the subjects with

TABLE 1. Multiple Logistic Regression Analysis of Relationship of Panic Attack History to Sexual Maturity and Age in 754 Sixth- and Seventh-Grade Girls

Variable	Parameter Estimate	SE	χ^2 (df=1)	p
Sexual Maturity Index ^a	0.8	0.2	12.2	0.0005
Age	-0.5	0.3	3.0	0.09
Interaction	0.2	0.3	0.8	0.38

^aOdds ratio=2.3, 95% confidence interval=1.4-3.6.

panic attacks was as follows: white, 37.5%; Hispanic, 37.5%; Asian, 12.5%; and other, 12.5%. The ethnic distribution of the subjects without panic attacks was white, 44.3%; Hispanic, 22.0%; Asian, 19.3%; and other, 14.4%.

The results of the multiple logistic regression analysis are presented in table 1. The adjusted odds ratio for the association between the Sexual Maturity Index and panic attack history was 2.3 (95% confidence interval=1.4-3.6); i.e., at each age a single point increase in the Sexual Maturity Index was associated with a more than twofold increase in the odds of having had a panic attack. There was no statistically significant effect of age or the interaction between age and the Sexual Maturity Index.

A striking result was the higher prevalence of panic attack history in girls at more advanced stages of pubertal development at any given age (see table 2). Of the 94 girls with a Sexual Maturity Index of 1 or 2, none reported having had a panic attack. Of the 100 girls who had completed puberty, represented by a Sexual Maturity Index of 5, 8.0% reported panic attacks. The increase in reported panic attacks with increasing sexual maturity was not accounted for by increasing age. At any age between 11 and 13, a history of panic attacks was more common in the more sexually mature girls.

DISCUSSION

It is important to note that although this study indicates an association between panic attack history and pubertal stage, it does not provide historical information concerning the exact point, during puberty or before puberty, at which any given subject experienced her first panic attack. Other limitations of this study include the cross-sectional design, the constricted age range of the sample, and the absence of boys. Boys' sexual development at any given age would not be comparable to that for the girls in this study, and we have no information about whether panic and puberty are related in boys. In addition, there was an ascertainment bias in that the subjects who completed both the interview and self-determined Tanner staging were different from the subjects who completed one or neither of the assessments. The noncompleters were significantly older and more commonly Hispanic than were the completers. Since noncompletion was due to ab-

sences and language barriers, the ascertainment bias may reflect attendance patterns and language-related bias rather than avoidance of study participation. Nevertheless, this ascertainment bias may render the findings less generalizable.

It is also important to realize that isolated panic attacks are not necessarily clinically significant. Which and how many of the girls in this study who have experienced one or more panic attacks will go on to develop panic disorder is unknown. Although girls who have had one or more panic attacks may be a high-risk population, longitudinal studies are required to elucidate the natural history of those who experience isolated panic attacks.

It is tempting to speculate that the increasing levels of sex hormones during puberty contribute to the increased occurrence of panic in the later stages of puberty. This study provides no empirical basis for supporting a hormonal explanation over a psychosocial hypothesis. The interaction of hormonal and psychological changes may be most important. Other possible explanations related to puberty include exposure to illicit drugs, separation fears, increased social anxiety, increased sexual activity, or the recently suggested possibility that the neurodevelopment of the noradrenergic system is related to the onset of panic (33).

An important developmental change that occurs during puberty is the emergence of the capacity for abstraction. Nelles and Barlow (8) have argued that the rarity of panic in childhood is related to stages of cognitive development. They contend that children may be incapable of making the necessary false connections between bodily sensations and catastrophic outcomes, which characterize panic sufferers. For example, believing that heart palpitations represent an impending heart attack may require formal operational thought in the Piagetian definition, which children have yet to acquire. On the other hand, evidence from case reports indicates that children do experience panic attacks which are phenomenologically similar to adults' panic episodes (13, 14, 21, 23) and that they respond to similar treatments (19, 21, 34).

Adolescence is a period of high risk for onset of many forms of psychopathology. For example, the incidences of obsessive-compulsive disorder (35), depression in

girls (36), anorexia nervosa (37), and suicide (38) rise abruptly during adolescence. Nevertheless, there remains a paucity of data regarding the role of puberty in the onset of these conditions. The results of this study suggest that assessing pubertal level should become standard in psychiatric risk assessment studies of young adolescents. In addition, efforts aimed at the prevention of morbidity related to panic might best be directed at peripubertal adolescents. More generally, this study reminds us that, although for most adolescents puberty signals the normal transition from childhood to adulthood, for others puberty may herald the beginning of adult forms of psychopathology.

Tics and Tourette's Disorder: A 2- to 7-Year Follow-Up of 54 Obsessive-Compulsive Children

Henrietta L. Leonard, M.D., Marge C. Lenane, M.S.W., Susan E. Swedo, M.D.,
David C. Rettew, B.A., Elliot S. Gershon, M.D., and Judith L. Rapoport, M.D.

Objective: This study examined a hypothesized etiologic relationship between Tourette's disorder and obsessive-compulsive disorder. **Method:** Fifty-four children who had initially participated in treatment protocols for obsessive-compulsive disorder (Tourette's disorder was an exclusionary criterion) were reevaluated 2–7 years later with a neurological examination and a structured interview to establish the presence or absence of tics and Tourette's disorder. The children's first-degree relatives (N=171) were also screened for tic disorders. **Results:** At baseline, 57% (N=31) of the patients had lifetime histories of tics. At follow-up, 59% (N=32) had lifetime histories of tics; eight of these (all males) met the criteria for Tourette's disorder (six had developed the disorder, and two, it could be argued in retrospect, might have met the criteria at baseline). The patients with lifetime histories of tics had greater anxiety, a higher ratio of CSF 5-hydroxyindoleacetic acid to homovanillic acid, and a younger age at onset of obsessive-compulsive disorder than those without tics. The patients with Tourette's disorder differed from other male patients only in having an earlier age at onset of obsessive-compulsive disorder. Of the first-degree relatives, 1.8% (N=3) had Tourette's disorder, and 14% (N=24) had a tic disorder. **Conclusions:** Except for their earlier age at onset of obsessive-compulsive disorder, the patients with Tourette's disorder were indistinguishable from those without. The apparent high rate of tics and Tourette's disorder in the subjects and their relatives is consistent with the hypothesis that in some cases, obsessive-compulsive disorder and Tourette's disorder may be alternative manifestations of the same underlying illness.

(Am J Psychiatry 1992; 149:1244–1251)

Obsessive-compulsive disorder has been reported in association with a number of basal ganglia disorders, specifically, Sydenham's chorea (1), post-encephalitic Parkinson's disease (2), Huntington's chorea (S. Folstein, personal communication), and Tourette's disorder (3). Of these, obsessive-compulsive disorder has been noted most often in Tourette's disorder; the more recent systematic studies have reported that one-third to one-half of adult (3–5) and child (6) patients with Tourette's disorder are afflicted. Studies of patients with obsessive-compulsive disorder also suggest a relationship between Tourette's disorder and obsessive-compulsive disorder; an

increased prevalence of chronic tics has been noted by several observers (5, 7, 8).

Other compelling evidence for a relationship between Tourette's disorder and obsessive-compulsive disorder comes from family studies of probands with Tourette's disorder (3, 5, 9, 10). Pauls et al. (3) reported that the rate of obsessive-compulsive disorder among 45 first-degree biologic relatives of 13 probands with Tourette's disorder without obsessive-compulsive disorder was 26%. This was higher than the expected rate in the general population and was similar to the rate for relatives of probands who had Tourette's disorder with obsessive-compulsive disorder. The mode of transmission of Tourette's disorder and chronic tics is consistent with autosomal dominant inheritance with incomplete penetrance and sex-influenced expressivity (10). Pauls et al. (3, 10) hypothesized that at least some forms of obsessive-compulsive disorder are etiologically related to Tourette's disorder and chronic tics and that obsessive-compulsive disorder may be an alternative phenotypic manifestation of the gene(s) responsible for Tourette's disorder. At present, however, the exact relationship between Tourette's disorder and obsessive-compulsive

Preliminary data from this study were presented in part at the Second International Scientific Symposium on Tourette Syndrome, Boston, June 17, 1991.

disorder is unknown, and there are no systematic studies of Tourette's disorder in family members of probands with obsessive-compulsive disorder.

The actual prevalences of Tourette's disorder and chronic tics are unknown, as no large general population samples have been systematically screened for tics. The prevalence of Tourette's disorder in selected populations has been estimated to be 2.9 (11), 5.2 (12), and 40 (13) per 10,000, but the studies have been limited by their sampling techniques. Tic disorders are more common than Tourette's disorder in the general population, and estimates have ranged from 4% to 6% (14-16) to 12% (17, 18). Sampling techniques and varied diagnostic criteria for tics limited these studies, and in several samples nonspecific nervous or unusual movements were included, which may have inflated the estimates.

This report concerns tics and Tourette's disorder at 2- to 7-year follow-up in 54 children and adolescents with severe primary obsessive-compulsive disorder for whom a diagnosis of Tourette's disorder, but not chronic tics, had initially been ruled out. We hypothesized that despite the initial exclusion of Tourette's disorder, some of the patients with obsessive-compulsive disorder would "develop" Tourette's disorder, given the reported association between the two disorders, the presence of tics at baseline among many patients, and the hypothesis that within families of probands with Tourette's disorder the two disorders are etiologically related. The study addressed the following questions. 1) What are the lifetime and current rates of Tourette's disorder and tics at follow-up in child probands with obsessive-compulsive disorder and their first-degree relatives? 2) Is there a characteristic demographic, clinical, laboratory, or familial pattern among probands with obsessive-compulsive disorder and Tourette's disorder or chronic tics that might elucidate a relationship between the conditions?

METHOD

Fifty-four children and adolescents with severe primary obsessive-compulsive disorder who had been consecutively admitted to clomipramine treatment trials conducted between 1985 and 1988 (19, 20) were contacted for follow-up evaluation. At baseline, these 36 boys and 18 girls had a mean age of 13.6 years ($SD=2.0$, range=7-19) and a mean age at onset of obsessive-compulsive disorder of 9.9 years ($SD=3.3$, range=2-16). A diagnosis of Tourette's disorder was an exclusionary criterion for these studies, but a chronic vocal or motor tic was not.

At follow-up, the 54 subjects with obsessive-compulsive disorder had a mean age of 17.4 years ($SD=3.0$, range=10-24). They were reevaluated 2-7 years (mean=3.4 years, $SD=1.0$) after baseline. Information was obtained for all 54 subjects, and 48 (89%) of the patients were seen in person. Information on the remaining six (11%) was available from at least two of the following sources: telephone interview with the patient ($N=3$),

family report ($N=6$), current private physician's report ($N=2$), and medical records ($N=3$).

At baseline evaluation, assessment of lifetime and current *DSM-III-R* tic diagnoses consisted of clinical interviews and administration of the Diagnostic Interview for Children and Adolescents (21) (including the tic section of the parent interview) to a parent and child, review of available medical records, and a neurological examination. Demographic measures, associated comorbidity, and scores on severity rating scales, including the National Institute of Mental Health (NIMH) global scales for obsessive-compulsive disorder, anxiety, depression, and functioning (22), have been reported by Leonard et al. (20). Interrater reliability (κ) between the two raters (H.L.L. and S.E.S.) ranged from 0.91 to 0.97 and is detailed elsewhere (23). Forty-three (80%) of the patients underwent lumbar puncture (24).

At follow-up, the measures were repeated, and the NIMH global obsessive-compulsive disorder score (22) was used as the follow-up rating of the severity of that disorder. Additionally, the Tourette syndrome/tics section-modified of the Yale Schedule for Tourette and Other Behavioral Syndromes (25) was administered to either the parent (about the proband) or the proband, and the Children's Global Assessment Scale (26) was completed. Twenty-two patients had a repeat lumbar puncture; however, those results have not yet been analyzed.

With the use of the Diagnostic Interview for Children and Adolescents (21) or the Schedule for Affective Disorders and Schizophrenia (SADS) (27) (according to the age of the person being interviewed), 170 of the probands' 173 first-degree relatives over 6 years of age were interviewed in person when the probands entered the study. In addition, a forensic psychiatric evaluation of one father was available. Thus, diagnoses were made for 52 mothers (mean age=44.7 years, $SD=4.2$), 51 fathers (mean age=47.6 years, $SD=5.3$), 30 sisters (mean age=17.2 years, $SD=4.6$), and 38 brothers (mean age=15.9 years, $SD=5.4$). (Because two sets of brothers were included among the 54 subjects, for the family data one brother was randomly assigned as the proband and one as the sibling for each family. Thus, 52 probands are referred to for the family data. It should be noted that none of the four brothers had a tic disorder.) Lenane et al. (28) previously reported that among the first-degree relatives of 46 of these 54 probands, 15 parents (17%) and three siblings (5%; age corrected, 35%) had lifetime histories of obsessive-compulsive disorder at baseline. Three additional cases were diagnosed subsequently, at the time of this follow-up. (Two fathers had not acknowledged obsessive-compulsive symptoms at the first evaluation, and one sibling developed them in the interim.) All relatives had been observed for tics and had been asked during the baseline clinical interview about the presence of motor and vocal tics; however, no formal neurological examinations or structured ratings of tics were obtained, other than the Diagnostic Interview for Children and Adolescents—

Parent Version (21) for the siblings. At follow-up, the Yale Schedule for Tourette and Other Behavioral Syndromes (Tourette syndrome/tics section-modified) (25) was administered to at least one parent of every family, who reported on all family members, in order to confirm the original tic status and to assess any changes. Forty-eight mothers, 12 fathers, four siblings, and 28 probands were reinterviewed directly about family members, and 27 families had more than one family member interviewed.

BMDP stepwise discriminant analyses with jackknife validation (29) were used to determine which baseline and follow-up variables best discriminated 1) between patients with and without tics and 2) among males with Tourette's disorder, chronic/transient tics, and no tics. This procedure controlled for an otherwise inflated error rate that would have occurred with the use of a large number of univariate tests. Comparisons of specific obsessive-compulsive disorder symptoms between patients with and without tics were made with chi-square tests.

Since not all first-degree relatives had passed through the risk period for developing illness, the rates of tics and obsessive-compulsive disorder were age corrected using known cumulative data on age at onset (30, 31).

We used a modified Stromberg method (32) to correct for each person's age according to the percentage of the risk period for each disorder through which he or she had passed. Statistical comparisons of age-corrected rates of illness between different groups were made with chi-square and Fisher's exact tests. The age of 15 years was arbitrarily assigned to adults who recalled an onset of tics in adolescence but could not be more specific (N=11).

Life table survival analyses that used BMDP program P1L were performed to compute the cumulative hazard function (probability of developing an illness by a certain age) for tics and obsessive-compulsive disorder in the first-degree relatives (29, 33, 34). This procedure yields more information than simple lifetime prevalence estimates, as it allows for the estimation of the risk of an illness at a given age within a given population. To assess the relative effects of several variables simultaneously on the relatives' survival function (not developing illness), the Cox proportional hazards model was used with BMDP program P2L (29, 34). Comparisons between male and female relatives on this hazard function could then be made using the Mantel-Cox statistic (33-35).

RESULTS

The Patients

At baseline, 16 (30%) of the 54 patients with obsessive-compulsive disorder had a current transient or chronic tic, and 31 (57%) had lifetime histories of tics (including the current status). At follow-up, 22 subjects (12 male and 10 female) had no lifetime history of tics, and 32 subjects (24 male and eight female) (59%) had lifetime histories of transient/chronic tics or Tourette's disorder; 17 (31%) had current diagnoses of tics. Of the 32 with lifetime tic diagnoses, eight (15% of the total of 54 patients) met lifetime diagnostic criteria for Tourette's disorder, 12 (22% of the 54) for chronic tics, and 12 for transient tics. At follow-up, from rereview of initial medical records and from additional information obtained from structured interview, it could be argued that two of the eight subjects with Tourette's disorder (all male) might have met the diagnostic criteria for Tourette's disorder at baseline. Thus, six (11%) of 54 subjects who did not meet criteria for Tourette's disorder at baseline "developed" Tourette's disorder in the interim.

Of the 32 patients with lifetime histories of tics, at baseline 17 (53%) also had lifetime histories of an anxiety disorder, seven (22%) had attention deficit hyperactivity disorder, and seven had oppositional/conduct disorder. Of the 22 patients without a lifetime history of tics, 10 (45%) had an anxiety disorder, five (23%) had attention deficit hyperactivity disorder, and four (18%) had oppositional/conduct disorder at baseline.

Among the 32 patients with lifetime histories of tics, nine (28%) had relatives with obsessive-compulsive

disorder, and 13 (41%) had relatives with tics. Among the 22 patients with no lifetime history of tics, seven (32%) had relatives with obsessive-compulsive disorder, and 11 (50%) had relatives with tics.

The sex of the subject, a family history of obsessive-compulsive disorder, a family history of tics, and all variables shown in table 1 were entered into the discriminant analysis. The statistically significant variables best able to distinguish the 32 patients with lifetime histories of tics from the 22 without were, in order of significance, a higher score (more symptoms) on the NIMH global anxiety scale at baseline, a greater baseline ratio of CSF 5-hydroxyindoleacetic acid (5-HIAA) to homovanillic acid (HVA), and a younger age at onset of obsessive-compulsive disorder. Together, these three variables correctly classified 81% of the patients with tics and 57% of the patients without tics, for an overall ability of 69%. There was no difference (by chi-square test) between the presenting major obsessive-compulsive symptoms of patients with and patients without lifetime histories of tics. Washing compulsions were the most frequently reported for both groups, followed by checking and repeating.

At follow-up, although all of the eight patients with Tourette's disorder met the *DSM-III-R* diagnostic criteria, the symptoms were mild. Only four patients were aware that they had a tic disorder, and only two had had a previous medication trial for the tics. All but one of the Tourette's disorder patients had lifetime histories of tics at baseline. Three had attention deficit hyperactivity disorder, one had learning disabilities (visual perceptual), and one had oppositional and conduct disorder. Three patients with Tourette's disorder had a first-degree relative with obsessive-compulsive disorder, and four had a family history of tics (one relative met criteria for Tourette's disorder). The primary presenting symptoms were typical for obsessive-compulsive disorder—specifically, washing rituals (N=5), hoarding (N=1), repeating (N=1), and scrupulosity (N=1).

To see whether the patients with Tourette's disorder differed on any measure (in the previous discriminant analysis) from those with chronic/transient tics and

from those without any tic diagnosis, a second discriminant analysis was performed. Only males were chosen for these comparisons in order to control for any confounding influence of gender. Only a younger age at onset of obsessive-compulsive disorder distinguished the group of patients with Tourette's disorder from the other two groups. Age at onset of obsessive-compulsive disorder distinguished 50% of the patients with Tourette's disorder, 80% of those with tics, and 0% of the patients without tics, for an overall rate of 46%. The mean ages at onset of obsessive-compulsive disorder for the eight boys with Tourette's disorder, the chronic/transient tic group, and the group without tics were 6.5 years (SD=3.5), 10.4 years (SD=2.9), and 11.3 years (SD=3.1), respectively. No significant differences between the three groups were found for the CSF measures: 5-HIAA/HVA ratios for the Tourette's disorder group, the transient/chronic tic group, and the group without tics were, respectively, 0.53 (SD=0.12) (N=3), 0.45 (SD=0.12) (N=11), and 0.40 (SD=0.05) (N=12).

The Families

At follow-up, three (1.8%) of the first-degree relatives (one father and two male siblings) met criteria for a lifetime diagnosis of Tourette's disorder. All three were evaluated in person to confirm the diagnosis. The three different probands whose family members had Tourette's disorder were in three separate patient diagnostic subgroups: obsessive-compulsive disorder and Tourette's disorder, obsessive-compulsive disorder with chronic tics, and obsessive-compulsive disorder without tics.

The age-corrected lifetime prevalence rates of obsessive-compulsive disorder and tic disorders (including chronic, transient, and Tourette's disorder) among the 171 first-degree relatives are presented in table 2. The most striking findings were the apparent high rates of tics (14%) and obsessive-compulsive disorder (17%) among the first-degree relatives of the probands and the fact that illness in relatives was unrelated to the sex of the probands. There were significantly more male rela-

^aThere were no significant differences in rates of illness in relatives by diagnosis of probands (chi-square or Fisher's exact test).

^bObsessive-compulsive disorder, tic, and Tourette's disorder diagnoses are not mutually exclusive.

^cCategory includes transient and chronic tics and Tourette's disorder.

^dAge-correction factor of tics was used for this category; two age corrections could not be made, and the conservative correction (that of illness with earlier onset) was chosen.

FIGURE 1. Tics and Obsessive-Compulsive Disorder by Age at Onset in 171 First-Degree Relatives of 52 Probands With Obsessive-Compulsive Disorder

tives than female relatives with tics and significantly more male relatives than female relatives with obsessive-compulsive disorder. As shown in table 3, the rates of illness (obsessive-compulsive disorder, tics, or Tourette's disorder) in first-degree relatives did not differ significantly according to proband status (no tics, tics, and Tourette's disorder) by chi-square test.

The Cox proportional hazards model was used to test simultaneously the effects of the probands' sex, age at onset of obsessive-compulsive disorder, comorbid attention deficit hyperactivity disorder, severity of obsessive-compulsive disorder, and severity of tics and the effects of the sex of the relative on the survival function (not having a diagnosis) of the relative. Testing each variable alone on this cumulative hazard function, we found that the only covariate with a significant impact on illness in the relative was the sex of the relative (obsessive-compulsive disorder, $\chi^2=4.67$, $df=1$, $p<0.03$; tics, $\chi^2=13.46$, $df=1$, $p=0.002$; obsessive-compulsive disorder or tics, $\chi^2=12.73$, $df=1$, $p=0.0004$). The cumulative effect of the five proband variables combined

failed as an overall regression model to make a statistically significant contribution to the hazard function (illness in the relative). Thus, of the six variables tested, only the sex of the relative was important in predicting the relative's possible development of tics and/or obsessive-compulsive disorder.

As a further confirmation, the Mantel-Cox statistic in life table analyses was used to compare male and female relatives on the cumulative hazard function (probability of developing tics or obsessive-compulsive disorder by a certain age). Male relatives were found to have a greater risk of both tics (Mantel-Cox statistic=13.83, $df=1$, $p=0.0002$) and obsessive-compulsive disorder (Mantel-Cox statistic=4.91, $df=1$, $p=0.03$) (figure 1). Similar results were obtained for developing either tics or obsessive-compulsive disorder when these were combined into a single analysis.

DISCUSSION

In this study, which addressed the question of the prevalence of Tourette's disorder and tics in child patients with obsessive-compulsive disorder and in their first-degree relatives, 59% ($N=32$) of the 54 subjects had lifetime histories of tics when evaluated at follow-up, although only one-third ($N=17$) actually had a current diagnosis. Methodological difficulties have led to widely varying estimates of the rate of tics and Tourette's disorder in the general population (11–18), so without systematic population studies, direct comparisons of our study group's rates with expected rates are not possible. However, the 11%–15% lifetime prevalence of Tourette's disorder in the patients with obsessive-compulsive disorder and the 1.8% rate in their first-degree relatives is higher than the published estimates of 0.03%–0.40% (11–13). Similarly, the lifetime rates of tics in the patients with obsessive-compulsive

disorder (59%) and their first-degree relatives (14%) are outside the reported range of 4%–12% (14–18). This seemingly high rate of tics and Tourette's disorder among the probands and their first-degree relatives lends support to the hypothesis that some cases of obsessive-compulsive disorder and Tourette's disorder may be etiologically related.

Illness (obsessive-compulsive disorder, Tourette's disorder, and/or tics) in the first-degree relatives was not related to either the sex or the tic status of the obsessive-compulsive disorder probands. This finding is consistent with that of Pauls et al. (10) among families of probands with Tourette's disorder; these authors reported that obsessive-compulsive disorder in the relatives was independent of the sex and diagnosis (with or without obsessive-compulsive disorder) of the proband with Tourette's disorder. In our current study, the male first-degree relatives had a higher rate of tics and of obsessive-compulsive disorder than did the female relatives. In contrast, Pauls et al. (10) reported that male relatives were more likely to have Tourette's disorder, and female relatives were more likely to have obsessive-compulsive disorder without tics, suggesting that obsessive-compulsive disorder could represent the part of the Tourette's disorder spectrum that is more frequently expressed in females. This difference between studies might be explained by the smaller number of families evaluated in our study or by the difference in proband status (obsessive-compulsive disorder versus Tourette's disorder).

A major limitation of the family portion of this report is that our data may underestimate the rate of tics. Although all relatives were seen in person and assessed for the presence/absence of tics, the reevaluation in person with a structured instrument was not done with every relative. Childhood tics that had subsequently resolved may not have been remembered by adults. Thus, if tics were not reported by the patient or family members and had gone "unnoticed" by the interviewer, they would not have been included.

It was hypothesized that at follow-up, some of the probands with obsessive-compulsive disorder might have "developed" Tourette's disorder, given the reported association between Tourette's disorder and obsessive-compulsive disorder and the presence of tics at baseline. Indeed, six males (11%) of 54 patients with obsessive-compulsive disorder who did not meet diagnostic criteria for Tourette's disorder at baseline did so at follow-up. Although it is not surprising that children with tics (who had not passed through their risk period) might subsequently develop Tourette's disorder, the presence of Tourette's disorder in 11% of the subjects seems high, particularly in light of the initial exclusionary criteria.

What distinguished the patients with obsessive-compulsive disorder and Tourette's disorder from those without Tourette's disorder? Only early age at onset of obsessive-compulsive disorder and male sex predicted who might develop Tourette's disorder. This is in keeping with the known predominance in males and the pos-

tulated sex-influenced genetic expressivity (3). Although we previously reported that the age at onset of obsessive-compulsive disorder was lower for boys than for girls (36), the significance of the earlier onset of obsessive-compulsive disorder in the patients with Tourette's disorder is not clear and has not been previously reported.

The patients with obsessive-compulsive disorder and Tourette's disorder were not distinguishable by the nature of their obsessions or compulsions. In general, the obsessive-compulsive symptoms were those typically seen, but a few patients exhibited behavior that was difficult to categorize as a ritual or tic. The categorization of the behavior was based on its complexity and the presence/absence of cognition preceding the action. Typically, a ritual is performed in response to a specific thought and a tic in response to an urge. Behaviors which remained difficult to classify clearly included that of a boy who would spit after the thought that his mouth had become contaminated by human body fluids and that of another patient who "compulsively" bounced a ball and touched his fingers in a rhythmic fashion because his "bones made him do it." Even if obsessive-compulsive disorder and Tourette's disorder are different manifestations of the same underlying illness, it appears that tics and rituals are for the most part clinically distinct and distinguishable. There may be a spectrum of behaviors, ranging from the classical tics of patients with Tourette's disorder to a mixed picture of tics and rituals to clear-cut rituals. Although this set of data does not help us truly address the distinction between tics and rituals, the clinical picture of obsessive-compulsive disorder was essentially not different among the probands with obsessive-compulsive disorder with and without Tourette's disorder.

An earlier age at onset of obsessive-compulsive disorder, a higher baseline anxiety rating (although not a *DSM-III-R* anxiety diagnosis), and a higher CSF 5-HIAA/HVA ratio distinguished the patients with obsessive-compulsive disorder and tic disorders from those without such a comorbid diagnosis. The meaning of the association between anxiety and tics is unclear, as the relation between anxiety and Tourette's disorder has not been systematically studied, and there was no increase in the number of individuals with anxiety disorders—just an increase in the anxiety rating. Perhaps anxiety and tics exacerbate each other or, less likely, they could both be manifestations of the underlying illness.

The increased CSF 5-HIAA/HVA ratio in the patients with obsessive-compulsive disorder and tics is consistent with hypotheses of altered neurotransmitters in Tourette's disorder and obsessive-compulsive disorder (24, 37–39). The present findings are in the same direction as those reported by Cohen et al. (37) for a group of six patients with Tourette's disorder who had a (non-significantly) higher 5-HIAA/HVA ratio than did a comparison group of eight patients with medical disorders. Although our patients with Tourette's disorder had a higher CSF 5-HIAA/HVA ratio than that of the male chronic and transient tic group (N=11), which in

turn was higher than that of the group without tics (N=12), none of these differences was significant. Only three of our eight patients with Tourette's disorder had lumbar punctures, so the small size of the study group may have contributed to the lack of a significant difference. Although no conclusions can be drawn from these nonsignificant results from a small number of subjects, it is tempting to speculate that tics and Tourette's disorder may be associated with disturbances of the serotonin/dopamine ratio.

This is the first large, systematic family study of tics and Tourette's disorder among probands with obsessive-compulsive disorder and their first-degree relatives. The high rate of tics and Tourette's disorder in the 54 patients with obsessive-compulsive disorder is consistent with the previously reported frequent association of these disorders. The apparent high rate of obsessive-compulsive disorder and tics in the first-degree relatives of the probands, independent of the probands' tic status, supports the hypothesis (3, 10) that in some cases, obsessive-compulsive disorder and Tourette's disorder may be alternative manifestations of the same underlying (genetic) illness. Even if the same etiologic mechanism may be responsible for some cases of Tourette's disorder and obsessive-compulsive disorder, the clinical picture of obsessive-compulsive disorder was indistinguishable among those with and without a comorbid tic diagnosis.

Differences in Neuropsychological and Academic Achievement Between Adolescent Delinquents and Status Offenders

Richard Famularo, M.D., Terence Fenton, Ed.D., Robert Kinscherff, Ph.D.,
Richard Barnum, M.D., Suzanne Bolduc, Lic.S.W., and Doris Bunschaft, M.A.

***Objective:** This study sought to determine whether neurocognitive factors could discriminate delinquents brought before a juvenile court in a large urban area from nondelinquent status offenders brought before the same court. **Method:** Psychological tests were administered to 216 adolescents, aged 13–15 years, presenting to a large urban juvenile court. One hundred ten delinquents (65 male and 45 female) were compared to 106 high-risk nondelinquents (65 male and 41 female) on the WISC-R subtests, the Wide Range Achievement Test, and the Memory for Designs Test. **Results:** Discriminant analysis revealed that the male delinquents could not be discriminated from the comparison group of male status offenders on the basis of scores on any of the measures. Among the female subjects, scores on reading, arithmetic, digit span, and picture completion subtests and the Memory for Designs Test differed significantly between groups, with some of the findings favoring status offenders and others favoring delinquents. **Conclusions:** Overall, the findings did not support the hypothesis that inferior intelligence is an independent risk factor for delinquent behavior.*

(Am J Psychiatry 1992; 149:1252–1257)

This study tested whether neurocognitive factors played a unique and significant role in predicting delinquent behavior in a group of high-risk, inner-city adolescents. Previous work has shown that delinquents have difficulty with numerous cognitive tasks, and some investigators have interpreted such findings to mean that neurocognitive deficits are implicated in the etiology of delinquency.

In an earlier study (1), the authors reported that delinquents presented with an average IQ deficit of one-half of a standard deviation (approximately 8 IQ points). Further research has indicated that delinquents exhibit deficits in IQ and other cognitive areas, regardless of race (2, 3) or social class (3–6). Moreover, the link between IQ and delinquency has been found in both retrospective and prospective studies (5–8) and across cultures. One retrospective study (8), based on 102 files randomly selected from a family court mental health clinic, revealed that one-third of the delinquent subjects were functioning in the “mentally defective

range” and one-third in the “low average to average range.” A prospective study of children (9) showed that self-reported delinquents had lower IQs than did nondelinquents. Self-report data also indicate that lower IQs and/or poor school achievement antedate the onset of delinquent behavior (7, 10, 11).

There is evidence to suggest that the lower IQs of delinquents are not merely the result of invalid or inappropriate testing. An analysis of male delinquents’ performance on the WISC-R revealed an acceptable level of internal consistency (12). Moreover, WISC-R subtest scores proved to be stable in a sample of children obtained from a juvenile court (13). After examining the factor structure of delinquents’ scores on the WISC-R subtests, investigators in one study concluded that differences in performance between delinquent and nondelinquent males “cannot be attributed to underlying ability structure” (14) and appeared to represent actual differences in cognitive performance capacities.

Delinquents exhibit a tendency to achieve higher scores on performance IQ than on verbal IQ. Previous research found that 70% of delinquent subjects had higher scores on the performance section of the WISC-R than on the verbal section (15). Moreover, hemispheric laterality, as measured by differences in verbal and performance scores, has been found to be related to delinquency (16). This phenomenon appears to have been related to the persistence of delinquent behavior among a group of 78 female delinquents whose cases had been tried in court; the rate of recidivism was found

to be significantly higher when performance IQ was greater than verbal IQ (17).

Studies associating neurocognitive deficits with delinquent behavior have not been limited to IQ testing. It has been reported that among male juvenile delinquents, auditory processing deficits and articulation disorders are common (60%) (18). Another study found deficits in academic skills to be among the most impressive covariates of antisocial behavior (19). Moreover, high rates of attention deficit disorder have been found among delinquents; the impaired capacity for sustained attention and concentration associated with this disorder has consistently been identified as an important risk factor for the development of conduct disorder and delinquent behavior (20–23). Finally, it has been reported that delinquents, with or without a history of attention deficit disorder, score significantly lower than nondelinquents on verbal, visual-spatial, and visual-motor integration skills (24).

A previous study (5) discerned a pattern among studies concerning neurocognitive factors and delinquency. The authors pointed out that "the functions most consistently cited as impaired have been verbal and executive (abstraction, planning, inhibition of inappropriate responses, mental flexibility, sequencing, attention, and concentration)," although relative memory deficits have been cited as well. They concluded that the consistency of findings "has been impressive and suggests a robust effect."

The etiology of the link between neurocognitive factors and delinquent behavior has been the subject of considerable speculation. Theoretical models, developed primarily from studies of antisocial adults, have proposed that neuropsychological factors, such as diminished autonomic reactivity with resulting "stimulus seeking" (25–28), may contribute to the development of antisocial and/or criminal behavior. Such behavior has also been attributed to impaired passive-avoidance learning patterns (29, 30) or a combination of neurological and developmental factors (31).

Another approach has been to emphasize the fact that neurocognitive deficits contribute to a variety of childhood problems and negative experiences which may function as risk factors for delinquent behavior during adolescence. These problems include school failure (3, 32), poor reading skills (33), impaired internalization of verbally mediated controls (34, 35), early alcohol use (36, 37), and poor peer relationships (38–40). Stressing that delinquency results from complex interactions among a number of variables, theorists such as Lewis (41) and Levine (42) have included neurological impairment as one of several risk factors in their models of aggressive delinquent behavior. In spite of the findings reviewed here and the theories that seek to explain them, some studies of this subject have failed to find a link between neurocognitive status and delinquency. One study followed children between the ages of 8 and 12 who had been classified as learning disabled, and no association was found between their neurological disorders and subsequent delinquent behavior during ado-

lescence and early adulthood (43). Moreover, an investigation of juvenile violent, nonviolent, and sexual offenders found no relation between neurocognitive profiles and the severity of violent behavior (44). Other studies (45, 46) have suggested that socioeconomic factors and family problems may account for the apparent relation between academic problems and delinquency.

Comparisons among the studies on this subject are difficult, since a variety of measures and methods of data analysis have been used, and groups representing differing degrees of antisocial behavior and/or delinquency have been compared with various "normal" groups. In many of these studies, the assessment of the effects of neurocognitive factors has been confounded by the fact that the delinquent groups have differed from the comparison groups on many potential risk factors, some of which may have mediated the apparent relation between neurocognitive status and delinquent behavior. Thus, although a majority of the evidence we have just reviewed indicates that delinquent behavior is correlated with neurocognitive deficits, it is not clear whether these deficits contribute directly to the etiology of delinquency or whether the relationship is mediated by environmental factors.

Much of the literature on this subject refers to "antisocial" behavior, without making consistent distinctions between criminal and noncriminal types of obdurate behavior. In legal terms, "delinquent" acts are those against property or persons which, if committed by an adult, would constitute misdemeanors or felony criminal offenses. In contrast, "status offenses" are acts that are considered inappropriate or annoying when committed by minors (truancy, running away, stubbornness, and disobedience) but that would not ordinarily constitute a violation of law if committed by an adult.

This study sought to determine whether neurocognitive factors can discriminate delinquents brought before a juvenile court in a large urban area from status offenders brought before the same court. Such a discrimination would indicate that neurocognitive factors are implicated in the distinction between the criminal and noncriminal members of a group of "antisocial" adolescents who share a common, high-risk environment and a proclivity toward problem behavior. This would be consistent with the hypothesis that deficits in IQ and/or neurocognitive performance serve as independent risk factors for criminal behavior rather than as markers for environmental factors which mediate their relationship with delinquency.

A further aim of this study was to determine whether, in an inner-city population at high risk for delinquency, there are gender differences in the manner in which neurocognitive factors act as risk factors for delinquency. Previous research has tended to focus on males, who are overrepresented among delinquent adolescents. No previous studies have compared the contributions of neurocognitive factors to male and female delinquency and used the type of comparison group that was used in this investigation.

METHOD

The study group included 216 adolescents (130 male and 86 female) referred to a large inner-city juvenile court clinic. All data were gathered by sequential chart review of records completed between 1983 and 1987. The records of all adolescents between the ages of 13 and 15 years were included in the study. Each of the 216 adolescents whose cases were represented in this study had been referred to the juvenile court's mental health clinic for psychometric testing. The reasons for referral were varied, including assessment of 1) diagnosis, 2) competency to stand trial, 3) appropriate school placement, 4) potential for harming self or others, 5) child abuse and neglect, 6) appropriate living arrangements, and 7) overall neurocognitive status. In addition to the psychometric testing, all adolescents received a clinical psychiatric interview.

The psychometric test battery always included the Wechsler Intelligence Scale for Children—Revised (WISC-R) (47), the Wide Range Achievement Test—Revised, Second Version (WRAT-R-II) (48), and the Memory for Designs Test—Revised (49). Additional tests, such as the Rey-Osterrieth Complex Figure Test (50), the Bender Gestalt (51), and the Hooper Visual Organization Test (52), were used as clinically appropriate during the study period. The 216 study subjects represent all for whom at least the WISC-R, the WRAT-R-II, and the Memory for Designs Test were completed and documented in the court records.

For the purposes of analysis, the subjects were divided into two groups: delinquents (N=110, 65 male and 45 female) and status offenders (N=106, 65 male and 41 female). Group membership was determined by the presence or absence of criminal conduct. The legal definitions of the two groups are as follows. A delinquent is defined as "a child between the ages of 7 and 17 who violates any city ordinance or town by-law or commits any offense against the law of the Commonwealth" (53). A status offender is an adolescent brought before the court on a petition seeking determination of whether he or she is "in need of services." The wording defining the legal status of such a petition is, "A parent or legal guardian of a child having custody of such child . . . may apply for a petition . . . alleging that said child persistently runs away from home or persistently refuses to obey the lawful and reasonable commands of said parents" or alleging "guardian's inability to adequately care for and protect said child" (54).

While truancy, running away, or "disobedience" may be perceived as "socially deviant" by some, such behavior is meaningfully distinguished from armed robbery, rape, or assault. Socially deviant behavior is a continuum, but one clear line is the difference between criminal and noncriminal behavior. In our society, the presence or absence of known criminal conduct is an extremely important developmental and social factor. While there might have been some within-group differences, the purpose of conducting this large group study was to

permit an investigation and comparison of group characteristics.

The ethnic composition of the 216 subjects was as follows: approximately 50% were black, 37% were white, 10% were Hispanic, and 4% came from other ethnic groups. A chi-square test revealed no significant difference in race/ethnicity between the delinquents and the status offenders. Fifty-four percent of the subjects were eligible for Medicaid; a chi-square analysis showed that the groups did not differ significantly in this regard.

In this study, the two groups were homogeneous in terms of specific geographic location, race, gender, age, and income status. The standard measurements used in the analysis have considerable reliability and validity insulation from "environmental" characteristics. Also, the extent to which factors such as income level, educational system, or race may have an impact on scores was moderated by the use of groups with substantially homogeneous socioeconomic status.

There might be individual and family factors that were not addressed by our study method but that are potentially important in the understanding of delinquency. These might include psychiatric diagnosis and family constellation. However, the measures we used remain valid and reliable across individual psychopathology and family constellation. The literature supports the existence of effects of differences in education, race, and income on standardized measures, and these were controlled for in this study.

RESULTS

Table 1 presents the results of a series of two-way analyses of variance (ANOVA) in which group (delinquents versus status offenders) and gender served as between-subject factors. Dependent variables consisted of scores on each subtest of the WISC-R, standardized scores on reading, spelling, and arithmetic from the WRAT-R-II, and the corrected score from the Memory for Designs Test. Scores on each of these measures are standardized with respect to age. The results of these univariate analyses yielded marginally significant group effects on the information, vocabulary, and comprehension subtests of the WISC-R, with the status offenders having the higher scores. The delinquents had higher scores on the digit span subtest and the Memory for Designs Test, although a higher score on the latter represents poorer performance and the possibility of organic dysfunction.

Statistically significant gender differences were observed on the picture completion and object assembly subtests of the WISC-R; the males exhibited superior performance. The males also showed marginally higher scores on the block design subtest. The females performed significantly better than the males on the coding subtest and the digit span subtest of the WISC-R, as well as the reading, spelling, and arithmetic subtests of the WRAT-R-II. A marginally significant Group by

Gender interaction was observed on the reading subtest of the WRAT-R-II, reflecting the fact that females outperformed males by 11 points in the status offender group, while the gender difference in the delinquent group was less than one-half of a point. No significant Group by Gender interactions occurred on the other variables.

There were no significant gender or group differences in full-scale IQ. This indicates that although skills and achievement differed in specific areas, the groups were well matched in terms of overall intellectual ability as measured by the WISC-R. Power calculations revealed that, given the sample size and an alpha level of 0.05, a difference of 8 IQ points could have been detected with a probability of 0.99 if such a difference existed.

The multivariate relationships between cognitive performance and group (delinquents versus status offenders) were examined by means of two stepwise discriminant analyses, one for the male and one for the female subjects. The cognitive variables from the WISC-R, the WRAT-R-II, and the Memory for Designs Test served as predictors, with group classification as outcome. Table 2 shows that the strength of the relation between cognitive performance and group classification varied markedly as a function of gender. For the male subjects this relationship proved to be so weak that no variables would have been included in the model if the 0.05 level of significance had been used as the inclusion criterion. In contrast, strong relations between predictors and outcome were observed for the female subjects. In order to determine whether the predictors combined in similar ways to predict male and female delinquent classification, a lenient inclusion criterion of $p=0.15$ was used, thus allowing marginally

significant variables to enter the model and providing a tentative assessment of the combined cognitive determinants of male delinquent status.

For the male subjects, only two variables (scores on the digit span subtest and the Memory for Designs Test) made even marginally significant contributions toward predicting group membership. The model consisting of these two variables fell short of statistical significance ($p=0.079$), with a canonical correlation of 0.26. In this model the delinquents were characterized by better digit span scores but greater difficulty with the Memory for Designs Test. Classification results revealed that only 55% ($N=82$) of the male subjects were correctly classified by this model, with 49% ($N=43$) of the delinquents and 62% ($N=39$) of the status offenders assigned to the correct groups.

For the female subjects, cognitive measures predicted group membership with a much greater degree of accuracy. Five variables contributed to the model: scores on the digit span subtest, the picture completion subtest, the WRAT-R-II reading and arithmetic subtests, and the Memory for Designs Test. The final model was statistically significant at the 0.001 level, with a canonical correlation of 0.57. As with the male subjects, delinquency was associated with superior digit span scores but inferior scores on the Memory for Designs Test. In addition, superior performance on the picture completion subtest with inferior performance on the reading and arithmetic subtests contributed toward classification as a female delinquent. Classification results revealed that 76% ($N=55$) of the female subjects were correctly classified by the model, with 75% ($N=28$) of the delinquents and 78% ($N=27$) of the status offenders assigned to the correct groups.

^aN=75 for group on which model was estimated (subjects with complete data on all predictors); N=82 for group used in classification results (subjects with complete data on all variables included in the final model).

^bN=55 for group on which model was estimated (subjects with complete data on all predictors) and for group used in classification results (subjects with complete data on all variables included in the final model).

DISCUSSION

This investigation differed from previous studies in using a comparison group of status offenders whose risk status on environmental and family factors was so similar to that of the delinquents that both groups had actually appeared before the same court. The crucial difference between the groups was that the members of one had been convicted of engaging in criminally delinquent activity, while those of the other had not. This study examined whether cognitive factors played a significant role in determining which adolescents fell into the delinquent group.

The univariate analyses, in which data from male and female subjects were analyzed together, provided only marginal evidence of a link between cognitive performance and delinquency. In these analyses the delinquents displayed superior short-term memory ability (as measured by the digit span subtest) relative to the status offenders. However, they exhibited relatively inferior performance on WISC-R subtests involving long-term memory (vocabulary, comprehension, and information) and showed greater evidence of dysfunction on the Memory for Designs Test.

These initial analyses provided strong evidence of a relation between cognitive performance and gender, with females showing a significantly higher level of performance than males on all three tests of academic achievement and on WISC-R subtests involving short-

term memory and symbol manipulation (digit span and coding). Males, on the other hand, displayed somewhat higher scores on WISC-R subtests involving abstract and/or spatial relationships (picture completion, object assembly, and block design).

In view of these gender effects, the discriminant analyses that examined the overall relation between delinquency and cognitive performance were performed separately for the male and female subjects. These analyses revealed that cognitive factors could discriminate female delinquents from female status offenders with a significant degree of accuracy. Female delinquency proved to be associated with lower achievement in arithmetic and reading, in spite of greater ability in short-term memory (digit span) and sequential reasoning (picture completion). Relatively poor performance on the Memory for Designs Test, which has been linked to organic dysfunction, was also predictive of delinquent status among females.

Since overall IQ was not significantly different between the delinquent and nondelinquent groups, these results cannot be attributed to a global concept of intelligence. Thus, although there were significant differences, they are inconsistent with the notion that inferior intellectual ability is an independent risk factor for delinquency among females. Rather, the pattern describing the intellectual performance of female delinquents appears to be one of underachievement relative to the status offenders.

The results of the discriminant analyses on the male subjects indicated that delinquency could not be predicted with any degree of accuracy on the basis of cognitive performance. Thus, this study provides no evidence to suggest that inferior intellectual ability plays a role in separating delinquent males from a comparison group exposed to the same environmental risk factors. The results of this study are consistent with those of earlier work in finding that delinquent adolescents exhibit a level of cognitive performance that is well below average. However, this study found that a nondelinquent comparison group exposed to the same environmental risk factors exhibited equally poor overall cognitive performance. Furthermore, although some significant group differences were observed, the findings did not suggest that the delinquents were characterized by inferior intellectual ability relative to the comparison group. Thus, when environmental factors are held relatively constant, cognitive deficits do not emerge as an independent risk factor for delinquency.

Intravenous Versus Intramuscular Atropine in ECT

Barry Alan Kramer, M.D., Anoshiravan Afrasiabi, M.D., and Vicki E. Pollock, Ph.D.

Twelve patients receiving ECT consented to random assignment to either intravenous or intramuscular administration of atropine for a total of 48 ECTs. There were no statistically significant differences between routes of administration in heart rate, blood pressures, or sialorrhea, but intravenous administration eliminated one injection per treatment and the development of dry mouth and tachycardia between the intramuscular injection and ECT. The authors recommend that atropine for ECT be administered intravenously.

(Am J Psychiatry 1992; 149:1258-1260)

Although not a uniform practice, administration of atropine to patients receiving ECT to decrease sialorrhea and prevent vagal-induced bradycardia or asystole is not uncommon (1). Atropine is given either intramuscularly 30 minutes before induction of anesthesia or intravenously 2 minutes before induction of anesthesia. Current practice is to give atropine intramuscularly (2, p. 94). Reduction of sialorrhea is maximized by intramuscular administration. However, given individual differences in distribution and duration of action of atropine, intramuscular administration before anesthesia may offer little protection against bradycardia or asystole in some patients (1).

The purpose of this paper was to compare the intravenous and intramuscular routes of atropine administration in patients receiving ECT.

METHOD

The subjects (N=12) were eight women and four men who were scheduled to receive ECT. Their mean age was 52.3 years (SD=19.2) (range=23-74). They were voluntary psychiatric patients with mixed diagnoses.

Presented in part as a New Research poster at the 143rd annual meeting of the American Psychiatric Association, New York, May 12-17, 1990. Received July 23, 1991; revision received Dec. 30, 1991; accepted Jan. 24, 1992. From the Department of Psychiatry and the Behavioral Sciences (Psychology) and the Department of Anesthesiology, University of Southern California School of Medicine. Address reprint requests to Dr. Kramer, LAC+USC Medical Center, 1934 Hospital Place, Los Angeles, CA 90033.

Patients with cardiac pacemakers were excluded from participation in the protocol because administration of atropine before ECT is often contraindicated in such patients. No changes were made in the psychotropic medications that the patients received during the study period. Two patients received tricyclic antidepressants (nortriptyline and amoxapine), two received a neuroleptic with an anticholinergic, one received a neuroleptic with a benzodiazepine, and seven received no psychotropic medication. All patients provided informed consent to their participation in the study.

The route of atropine administration was randomized beginning with the second and ending with the fifth ECT, with the constraint that each patient undergo two intramuscular and two intravenous sessions. The first ECT was not studied due to the elevated anxiety patients typically have before the first treatment. In each of two sessions, intramuscular atropine (1.0 mg) was given in the gluteus muscle 30 minutes before anesthesia induction or intravenous atropine (0.6 mg) was given 2 minutes before anesthesia induction. Anesthesia consisted of methohexital, succinylcholine, and hyperoxygenation. ECT was administered with the MECTA SR-I with bilateral electrode placement.

The ECT nurse, blind to route of atropine administration, recorded blood pressure and heart rate before atropine administration, before methohexital sodium administration, and 5, 15, and 30 minutes after ECT. Level of confusion was clinically assessed globally as present or absent. Post-ECT secretions were categorized by the nonblinded anesthesiologist (A.A.) on a 3-point scale on which 0=not excessive, 1=moderate but requiring no clinical intervention, and 2=copious, requiring clinical intervention.

RESULTS

The 12 patients received a total of 48 study ECTs. Twenty-four treatments followed intramuscular atropine and 24 treatments followed intravenous atropine. Analyses of covariance with repeated measures were used to assess the route of administration (intravenous versus intramuscular) and time (before the administration of methohexital sodium versus 5, 15, and 30 minutes after ECT) with Greenhouse-Geisser adjustments for the degrees of freedom (3). The covariate in each analysis was the value before the administration of atropine, and separate analyses of the systolic and diastolic blood pressure and heart rate were performed. The dependent variables were the means of each subject's blood pressure and heart rate obtained in the two intravenous sessions and in the two intramuscular sessions.

Consistent with the known effects of ECT, significant changes in blood pressure (time main effects: systolic, $F=14.02$, $df=3, 29$, $p<0.01$; diastolic, $F=3.77$, $df=2, 20$, $p<0.05$) and heart rate ($F=5.03$, $df=2, 20$, $p<0.02$) occurred. These consisted of transient increases of blood pressure and heart rate 5 minutes after ECT, followed by gradual reductions to pre-ECT levels approximately 30 minutes after ECT.

The differences between route of administration and blood pressure and heart rate changes following ECT did not attain statistical significance at conventional alpha levels. Two trends, however, were evident. Elevated systolic blood pressure tended to persist after ECT for a longer time period under intravenous than under intramuscular administration (5–30 minutes after ECT) (administration by time interaction, $F=1.93$, $df=2, 25$, $p=0.16$). For heart rate, the increase 5 minutes after ECT tended to be larger under intravenous than under intramuscular administration (administration by time interaction, $F=1.75$, $df=2, 25$, $p=0.19$). Secretions and bradycardia did not differ substantially under intravenous compared with intramuscular administration.

DISCUSSION

There were no statistically significant differences in blood pressure, heart rate, or secretions between intramuscular and intravenous atropine. Although there was a trend for systolic blood pressure elevations to persist longer under intravenous conditions compared with intramuscular, it did not reach statistical significance. Similarly, larger transient heart rate increases occurred 5 minutes after ECT under intravenous than under intramuscular administration, but these differences were not statistically significant.

Because the number of subjects evaluated in the present study was relatively small, the differences that might have occurred in blood pressure, heart rate, and secretions following intravenous, as opposed to intramuscular, atropine administration may not have been sufficient to attain statistical significance. Thus, we can-

not definitively discount the possibility that our failure to document differences between intravenous versus intramuscular administration reflects low statistical power (or, equivalently, that our results contain type II error). In addition, because therapeutic rather than scientific goals had precedence in this study, the anticholinergic properties of the medications that some of the patients received may have reduced the likelihood that statistically significant results would be obtained.

This report does not attempt to resolve the issue of whether atropine should be used in conjunction with ECT. This controversy has existed for a long time. In 1964, Cropper and Hughes (4) questioned the wisdom of "routine" atropine premedication, but the overwhelming larger body of opinion favored its use. The intravenous route provided the maximal vagolytic action at the time of the stimulation. More recently, Wyant and MacDonald (5), among others, have raised questions about the routine use of atropine during ECT. Their patients were receiving unspecified psychotropic medications with an unknown degree of anticholinergic protection. Miller et al. (6) observed less vagal arrhythmias in 44 patients when they received atropine than when they received placebo before ECT. The frequency of ventricular arrhythmias was unaffected. Tachycardia and confusion are known side effects of atropine. Relaxation of the lower esophageal sphincter with the resultant risk of gastroesophageal reflux and aspiration is also of concern.

Clement (7) reported that one out of 100 patients receiving intravenous atropine 75 seconds before ECT had severe bradycardia and that 22 receiving atropine subcutaneously 30 minutes before ECT developed severe bradycardia or asystole. The less efficient vagal blockade may be related to the fact that in a "busy clinic," 30 minutes could be anywhere from 10 to 80 minutes. Patients in that study liked the lack of dry mouth and unpleasant tachycardia before the treatment at a time when anxiety was high and they could not be premedicated.

A standard anesthesia text states, "Prevention of reflex bradycardia seems unlikely with the timing and dose of intramuscular anticholinergic typically administered for preoperative medication" (8, p. 388). Rich et al. (9) recommended a subcutaneous dose of 1.0 mg of atropine because they noted no change in ECG abnormalities following doses ranging from 1.0 to 2.5 mg. Hence, there was no advantage of higher doses.

CONCLUSIONS

Three procedural factors favor intravenous over intramuscular administration of atropine. First, intravenous atropine administration permits more accurate estimation of the time of its effects than does intramuscular administration. This is important because in clinical settings, many external factors can lengthen or shorten the time interval from the intramuscular atropine until the ECT. Second, patient comfort is greater with intravenous atropine. The 30-minute interval before the ECT is a period of

great anxiety for many patients, and the tachycardia and dry mouth that patients experience during this interval with intramuscular atropine can exacerbate their anxiety. Third, there are twice as many punctures with intramuscular than with intravenous administration because the latter can be given through the same intravenous line as the anesthesia. In addition to reducing the patient's pain, the intravenous administration lessens the chances of injury and work for the staff.

LEADERS AND THINKERS

Working With Dr. Schweitzer, by Louise Jilek-Aall, M.D. Blaine, Wash., Hancock House, 1990, 208 pp., \$16.95 (paper).

"Schweitzer, Albert, Alsatian physician, philosopher, theologian, and musician, in French Africa, 1875-1965." This is how the name index of my dictionary sums up the life of one of the most remarkable men of the twentieth century, a man called a saint by some and a self-righteous tyrant by others. As a physician he made no great medical discoveries but, rather, established a modest hospital in 1913 in the backwater village of Lambaréné in Gabon, West Africa. As a philosopher he expressed an optimistic belief that nature was indifferent and that each person had a duty to bring some portion of the misery in the world to an end. As a theologian he wrote shocking psychiatric and historical studies of Jesus but found personal strength and guidance in the Christian message of love. As a musician he was a biographer of Bach and an accomplished organist.

In 1954 Dr. Schweitzer went to Oslo to receive the Nobel Peace Prize. A torchlight procession was led by medical students from the old university to the city hall. When the laureate and his wife stepped out onto the balcony, they were greeted by 20,000 well-wishers who spontaneously expressed their warm feelings by singing an old Norwegian hymn. Louise Aall, a premedical student, was in the throng. Seven years later she was toiling with her hero in the tropical heat.

Louise Aall studied tropical medicine in Switzerland before working as a bush doctor in Tanganyika (now Tanzania). In 1960, at the request of the International Red Cross, she worked in the war-ravaged Congo. A year later, exhausted from work, she planned a leisurely vacation by boat around Africa back to Tanganyika. While waiting for her boat she decided to fly to Lambaréné for a brief visit.

Dr. Schweitzer's hospital, famous throughout the world, was nothing more than a series of wooden buildings with rusted iron roofs. Dr. Aall introduced herself to Mlle. Mathilde Kothmann, the secretary whose approval was necessary for anyone desiring to meet Dr. Schweitzer, and that evening Dr. Aall was invited to dine with the good doctor. Dr. Schweitzer sat at the center of a long table with hospital physicians to his right and nurses to his left. Guests were seated on the other side of the table. Dr. Aall was given the most privileged position, opposite the 86-year-old physician. It was a magical event. After the meal Dr. Schweitzer pushed aside the plates, read a passage from a huge Bible, and discoursed on the apostles' reaction to the death of Jesus. He then walked to a piano and played several sing-along tunes as well as his own compositions. Suddenly he said, "That's enough for today. Good night."

Dr. Aall stayed in the staff quarters, which had no electricity or running water. Mosquito screens took the place of walls in the front and back of the building, "a thin and fragile barrier

between oneself and the untamed nature outside." That night and almost every night thereafter she was lulled to sleep by the crystal clear melodies of Bach that came from Schweitzer's organ.

A measles epidemic was raging, and Dr. Aall could not resist the invitation to work at the hospital. Soon she was surrounded by coughing, moaning, and dying children. Dr. Schweitzer sat at a large table in the center of the clinic and, amid the turmoil, wrote letters and prepared the evening's lecture while overseeing the clinical work and offering advice in difficult situations. The operating room presented special problems at times. Once a lizard, overcome by ether vapors, fell from the ceiling into a patient's abdomen. Another time, to save a patient with a ruptured ectopic pregnancy who was bleeding dangerously, Dr. Aall, using a strainer and anticoagulant, scooped up the blood from the patient's abdomen and infused it back into her through an arm vein. The woman recovered without any complications.

Plane loads of tourists would descend on the hospital, interfering with patient care. "We loathed the questions of these tired-looking travelers who seemed to always be in such a hurry and never took time to listen to our answers. Equipped with a camera, they hunted for something to shoot, thoughtlessly photographing patients in pain, and even dying patients." Dr. Schweitzer's favorite visitor, however, was Marie-Anne. "This extraordinary lady was of the type men only like when her charm and caprices are for them exclusively and whom women, especially hard-working ones, find difficult to tolerate." Dr. Aall was asked to take the lady on a boat trip with oarsmen from the leprosy compound. Marie-Anne took umbrage on this trip and, insulted, shortened her visit, giving Dr. Aall "an indelicate souvenir selected in a vengeful mood." Intrigued, I called Dr. Aall but she would not reveal what the present was, although she did indicate it was quite gross and said, "Who but Dr. Schweitzer could appreciate Marie-Anne?"

Mentally ill patients were cared for by Dr. Friedman, a Jewish doctor who had survived the Nazi concentration camps. When a servant became ferociously paranoid, Dr. Aall insisted he be brought to a special compound, where he was locked in an empty, windowless room (a heavy wooden grill on the door allowed in light and fresh air) that was "built solid enough to withstand the onslaught of even the most violent psychiatric patient." Despite incessant use of medication the patient worsened. His family, convinced that he was possessed by demons, talked of releasing the demon by making a hole in his chest. Dr. Schweitzer would have none of this, however, and went to the patient and said, "It's enough! You have shown us your sorrow and you went to the limits of what a human can endure. Nobody wants to harm you; we all wish you to be with us. Come back to us or you will die. To atone for what you did to your wife, you have to live! Show us that you are a man of courage as well as a man of heart." With those words the spell was broken and the patient recovered.

Dr. Jilek-Aall has filled the pages of this upbeat, tender book with lively anecdotes about the everyday life of Dr. Schweitzer, bowed by age but unyielding in his humanity. Although many books have been written about Lambaréné, this one stands out for its vivid simplicity and insights into the customs, mentality, and relationships of those who worked under the tutelage of this great old man of Africa.

ARMANDO R. FAVAZZA, M.D.
Columbia, Mo.

Looking Back: Memoirs, by Lou Andreas-Salomé; edited by Ernst Pfeiffer; translated by Breon Mitchell. New York, Paragon House, 1991, 226 pp., \$18.95.

Alluring to men and compassionate with women, Lou Andreas-Salomé (1861–1934) cut a wide swath across the intellectual terrain on both sides of the artificial divider called *fin-de-siècle*. Among her most notable conquests were Nietzsche, Rilke, and the Freuds (both Anna and Sigmund). Her marriage remained unconsummated while she sought the companionship of numerous “lovers”—how overtly sexual they were is not disclosed. Her primary love was self-centered: “I intend to shape my life for myself, no matter how it turns out.” Her memoirs are like inner dialogues, exasperatingly verbose, but they reveal a wonderfully complex, unconventional, feminist mentality.

Louise von Salomé grew up in St. Petersburg, the last of six children and the only girl, pampered by her Russian servants, adored by her brothers and her elderly father, a German-Baltic military officer. Her mother was “not a natural friend.” Lou was an adolescent when her father died. Almost immediately she attached herself passionately to a Dutch Protestant cleric, Hendrik Gillot, who reciprocated her love and offered to abandon his wife and children to marry her. They did not marry, but he instructed her in philosophy and converted her to his faith. “Now all loneliness is at an end . . . he is He,” she writes. This blend of spiritual and erotic ecstasy was to characterize all of her subsequent love affairs.

Gillot, for whom she wrote sermons, officiated at her marriage at age 25 to the brilliant but rather disorganized Karl Andreas, a professor of Oriental and Indo-European languages who was 15 years her senior. There was illness on both sides. Lou was exceedingly “nervous,” coughed blood, and sought treatment at various spas. Karl attempted suicide by stabbing himself in the chest the night before the engagement. He nearly died. Their marriage of convenience gave him security for his scholarship and provided a home base for her notorious adventures. Before and after the marriage, Lou lived and traveled with Paul Rée, a brilliant young philosopher and medical student, joined from time to time by the charismatic Nietzsche, who allegedly also wanted to marry her. “What does it mean to get close to a person?” she asks, and answers, “a coming together that takes us somewhere we didn’t expect to go: one of those precious relationships that falls outside the realm of what can be precisely analyzed.”

Her most intense and stressful relationship by far was with Rainer Maria Rilke. “His identification with everything misbegotten and rejected becomes an absolute part of his emotional makeup, in a manner which probably occurs only in a creator unable to create.” To help him overcome his work inhibition, she took him to her native Russia, twice visited Tolstoy, and wrote poetry for and with him. “We were but a single person.” Rilke’s profound anxiety, restlessness, impatience, self-debasement, preoccupation with death and the oc-

cult, morbid sensitivity, distorted body image, and tendency to throw himself to the ground in frustration suggests a borderline personality. Lou thought of him as “the first truly real person in my life,” but later regretted having lacked the necessary clinical skills to treat him properly.

She sought training first with Adler, then with Sigmund Freud, and from psychoanalysis acquired “the tendency not to allow oneself to be distracted by general considerations about whether the end results are pleasing or not, to focus totally on the precise investigation of the object and the special case, whatever the outcome might be.” She muses on the meaning of sublimation: “Even the most forbidden sexual perversions, ‘in spite of their abominable effects,’ could be termed sublimations—in that, fixated at the infantile stage of sexuality, they remained diversions from the goal of physical maturity.” On Freud: “It was his rational approach to scientific research which yielded the discovery of the irrational at the end of the path he followed so unflinchingly.” Meetings of the Vienna Psychoanalytic Society felt to her “like a gathering of brothers and sisters.” She last visited Freud in 1928. Two years later her husband died at age 84. Her remaining years were spent seeing patients, reminiscing about herself and the men in her life, and writing. Altogether she produced 17 books, including novels, collections of short stories, plays, poems (some are reproduced in this book), a monograph on “The Erotic,” and psychoanalytic essays.

Her memoirs have appeared in three German editions since 1951, but this is the first English translation. It is done with great thoroughness and includes 62 pages of notes by the editor, a personal friend to whom Lou bequeathed all of her papers. This is a book for specialists and literary scholars, but whoever reads it will be touched by the author’s rare inner vision and astonishing intellect. Her conclusion, in facing death, is that “existence remains for me a picture puzzle: and yet we too are included within its open secret.”

PETER F. OSTWALD, M.D.
San Francisco, Calif.

Vygotsky’s Psychology: A Biography of Ideas, by Alex Kozulin. Cambridge, Mass., Harvard University Press, 1991, 279 pp., \$29.95.

Along with Luria, Lev Vygotsky has been the leading intellectual force in Soviet psychology. His activities were limited to approximately 20 years (1916–1934) and were suppressed during much of this time because he did not readily conform to the prevailing and all-encompassing Marxist ideology (talk about “political correctness”). The author, a Moscow-born physician who teaches psychology at Boston University, has attempted to summarize Vygotsky’s work and to place it in the larger context of postrevolutionary politics in Soviet Russia and Vygotsky’s relationships with other Russian and Western thinkers.

This book may have tried to accomplish too much. For instance, in just a few pages one finds aesthetic theory, psychoanalysis, Hegelian philosophy, and Marxist theory interwoven with neuropsychology, psychiatry, and child development. Although this range of topics reflects the broad interests of Vygotsky himself, I think the book would have benefited from a more critical review of those domains of Vygotsky’s scientific work which could be evaluated in terms of the empirical findings of his group and other researchers both past and present. Instead, the book, at least in part, seems implicitly devoted to demonstrating that Vygotsky not only

directly influenced—and was influenced by—a large number of individuals but also presaged the bulk of enlightened psychological research of the twentieth century. Leaving aside the merits of this claim, it requires the author to review the writings of a large number of other scholars, such as Piaget, Luria, Leontiev (Vygotsky's student), Bakhtin (the Russian philosopher and philologist), Heinz Werner (the German-American developmental psychologist), and Freud, just to name a few. This leaves the reader with a potpourri of rather abstract summaries of ideas that are dense and, at times, difficult to digest, in contrast to Vygotsky's translated writing, which is lucid, provocative, and always refreshingly "close to the data" of actual subjects.

A series of principles and assumptions are highlighted—that actions are precursors to thought, that human intelligence is highly social in origin, and that language is the plinth of human consciousness. There is, however, no critical evaluation of these points of view. Perhaps this is acceptable for a book that is intended to be a kind of intellectual history, but readers are on their own in deciding what should be distilled out for the psychological inquiries of today and tomorrow. On a more positive note, what also shines through is the heroic character of a man who always dared to go his own way even when he knew the price he would pay. In the face of a truly anti-human polity, Vygotsky never abandoned the hope of achieving a truly human psychology that encompassed higher mental functions such as consciousness and creativity.

Two major concepts that are pure Vygotskian—"inner speech" and the child's "zone of proximal development"—are dealt with admirably in this book. The discussion of Vygotsky's work with schizophrenic patients and retarded children is succinct and informative.

It would be fascinating to know more of the personal biography of Vygotsky. This book contains an interesting description of his family of origin, his university days, and the poignant moment of his death, but one wants to know more about the man behind the intellect. I wonder, for instance, if there are surviving letters or students' notes that would help bring Vygotsky more vividly to life again. I also would like to know the nature and status of his untranslated writing—my impression is that a great deal of valuable material remains out of reach.

An important historical lesson of this book is that the science of psychology, like other kinds of science, can be influenced in subtle and not so subtle ways by intellectual, philosophical, and political ideologies. This leads Kozulin to ask questions about the priorities and direction of psychological and psychiatric research in the United States. For instance, he questions the reluctance to rigorously tackle the more "human" aspects of mental activity such as creativity and symbolic process. Such questions are worthy of serious consideration.

RALPH E. HOFFMAN, M.D.
New Haven, Conn.

CHILD PSYCHIATRY

The Self in Transition: Infancy to Childhood, edited by Dante Cicchetti and Marjorie Beeghly. Chicago, University of Chicago Press, 1991, 383 pp., \$34.95.

This book is the outcome of a conference held at Harvard University in November 1985. It presents research on the self

during the transition from infancy to adulthood. Clinicians may be misled by the title to expect to read about ideas concerning transitional phenomena. Although Winnicott is quoted relatively often, his concepts about the transitional object and its role in emotional development, which would include the progressive integration and differentiation of the self, are not emphasized. Rather, this scholarly volume examines the "interactions among biological, psychological, and sociological factors and of conducting assessments of functioning that span multiple domains."

Some of the authors, especially Stechler, focus on the psychoanalytic model and review current theoretical revisions, such as the abandonment of drive theory, and their relevance to our concepts of the development of the self. For the clinician, these are the most relevant sections because they have many implications about psychopathology as it is understood in terms of defects in psychic structure rather than predominantly in terms of intrapsychic conflict. The self or, as many psychoanalysts would say, the self-representation is a central core of the mental network and undergoes specific vicissitudes in the genesis of psychopathology as a structure and as a response to psychic trauma. It is clinically relevant no matter how it is defined, either as a central core or a supraordinate organization that embodies all aspects of psychic structure and interactions.

The editors begin by giving an excellent overview of the papers that follow as well as stressing the importance of the task they have set themselves. The editors and the authors do not limit themselves to clinical issues. Many of them come from a broad academic tradition, and this is expressed in their writings. Most of the chapters are straightforward and clearly written, but some are weighty and pedantic and tend to be burdensome rather than enlightening. Fortunately, they are in the minority, and I confess this assessment may, in part, be due to my bias. I prefer a clinically oriented conceptual system that has relevance to the treatment process. To me, the examination of psychic structures such as the self is most rewarding when it is placed in a clinical context. Perhaps this is generally true of clinicians' reactions.

I cannot discuss all of the chapters in this book because of space. I will briefly touch on some of the topics to give the reader the flavor of the book. The first two chapters after the introduction are psychoanalytically oriented. Stechler believes that the mode of resolving conflict becomes part of the self. This would indicate that adaptive and defensive patterns as they are consolidated in the ego's executive system contribute to the structure of the self-representation. This includes successful as well as unsuccessful adaptations and places the self in an operational perspective. Emde and Buchsbaum stress that the development of the self moves in the direction of autonomy and that this occurs in the context of connectedness, which means object relatedness. Other authors focus on cultural factors, the effects of social phenomena, and the linguistic approach in the development of the self.

This book covers many diverse topics reflecting the special interests of the behavioral scientists who are the authors. Some of the chapters will be more meaningful than others depending on the reader's orientation. The book ends on a seriocomic note that should capture the interest of most of us. Kagan presents a fictionalized dialogue between an older and younger philosopher, often witty and humorous, which recaps the difficulties involved in the study of the self.

PETER L. GIOVACCHINI, M.D.
Chicago, Ill.

The Psychoanalytic Study of the Child, vol. 45, edited by Albert J. Solnit, M.D., Peter B. Neubauer, M.D., Samuel Abrams, M.D., and A. Scott Dowling, M.D. New Haven, Conn., Yale University Press, 1990, 546 pp., \$55.00.

The Psychoanalytic Study of the Child has been one of the few central and essential journals of psychoanalysis since its first volume was published in 1945. Founded and managed at first by Anna Freud, Heinz Hartmann, and Ernst Kris, its editorial board and contributors were from the start outstanding psychoanalysts, many of whom made regular and particularly important contributions in its pages.

The last of its 12 original editors died last year, but its tradition and contributors have remained strong under subsequent editors, through three publishers, and through an era of markedly diminished power and influence of psychoanalysis over the past 20 years. The major excitement and centrality of the first 20 or so volumes are no longer there, and some articles in some recent volumes have seemed to be coasting, adding little. However, brilliant and important articles are still there, and in annual volume after annual volume high levels of clinical intelligence, seriousness, complexity, and integration are nearly always still there.

Let me state an interest, lest it be considered a blinding bias: I had a close family and family-friend connection to the editors and many of the contributors for the first few decades of *The Psychoanalytic Study of the Child*; I still have some friendships and friendly acquaintanceships with several current editors and contributors.

Volume 45 has 26 chapters grouped into seven areas: Psychoanalytic Theory, Development, Clinical Contributions, Transference and Countertransference, Self-Esteem and Shame, Termination of Analysis, and Applied Analysis. Child and adolescent issues are prominent, but the volume is not, nor has *The Psychoanalytic Study of the Child* ever been, just about children. Most of the authors are American, plus several Britons and Israelis. Striking to anyone used to reading current psychiatric journals, at least half a dozen carefully detailed case histories are presented and discussed in this volume; one gets the sense of several complex troubled people being well understood and treated over time (see, for example, the chapters by Gavshon, Cohen, Harrison, Ablon, Kaufman, and Lax).

One also gets the sense that even in this decade in which psychiatry often celebrates brain far more than mind, and despite notorious problems with verifiability of analytic hypotheses, psychoanalytic theory is still alive and growing. Gender, ego ideal, entitlement, object relations, attachment and separateness, fantasy, somatization, self-esteem, shame, termination—all receive worthwhile theoretical contributions in the present volume. Anton Kris's chapter, "The Analyst's Stance and the Method of Free Association," is, with its own careful scientific clinical stance, a model of wise theory building.

The chapters in the Self-Esteem and Shame section add to a currently overdue and lively area of exploration, but one might wish some firmer editorial hand had shaped the sprawling chapter by Yorke et al.; the brief chapter by Abrams that follows might, in an ideal world, have been built into, and helped shorten, the previous chapter.

In the section on Termination of Analysis, Jack Novick continues his clear work and adds a provocative potential bridge from child toward adult analysis.

There is a chapter on *The Secret Garden*; a somewhat self-preoccupied chapter on *The Velveteen Rabbit*; a good idea not

wholly shaped and carried out about Alain-Fournier and *Le Grand Meaulnes*; and a chapter by Lenore Terr on Virginia Woolf. I read with pleasure anything that Dr. Terr writes, but (despite its witty title) I found her discussion of Woolf less careful and persuasive than her brilliant earlier work on Poe, Magritte, Hitchcock, Bergman, and King.

One cannot fairly summarize 26 chapters in a brief review, but I can say that although I approached reading volume 45 of *The Psychoanalytic Study of the Child* as a duty, it soon felt like a rekindling of opportunity. I felt energized by reading this volume.

LAWRENCE HARTMANN, M.D.
Cambridge, Mass.

Psychosocial Issues in Day Care, edited by Shahla S. Chehrizi, M.D. Washington, D.C., American Psychiatric Press, 1990, 285 pp., \$38.00.

The 16 chapters in this volume are grouped under five headings: Developmental Considerations and Day Care, The Relationship Between Parents and Child Care Providers, Pediatric Issues in Day Care, Child Abuse and Day Care, and National Policy and Day Care. The individual chapters are written by clinicians and researchers with substantial experience in their respective fields. The breadth of the approach adopted by the editor makes this a valuable book, especially for those not immersed in day care issues, because it illustrates very clearly how complex many of the issues are, ranging from national social policy to concerns about the individual child, parent, and day care provider.

Zigler and Freedman, in the opening chapter, document the crisis in child care in the United States, including the lack of a national public policy based on developmentally sound practices and the high cost of good quality day care, which in many communities is not available at any price. The harm done to the development of infants and young children who are in day care of poor quality appears clear. There are excellent brief descriptions of current types of day care and a plan for developmentally sound practice. Zigler and Freedman believe that, in spite of their magnitude, the problems are not insoluble. The importance of a parental leave policy as an alternative to infant day care is outlined. The authors also advocate that the "school of the 21st century" be created as a return to the concept of the school serving as a local center for all the social services required by the community, including day care, and note that a number of demonstration schools are now in operation.

Carollee Howes summarizes current research on early child care, and Jay Belsky analyzes developmental risks associated with infant day care. Howes's clear presentation of research issues is particularly helpful to readers not familiar with the field. Three aspects of child care that emerge from child development research as important in facilitating optimal development are especially congenial with the views of the readers of this journal: 1) the stability of the child care arrangement, 2) the quality of the child care, and 3) the interaction between family characteristics and child care. The discussion of the multidimensional influences of early child care on the development of children recognizes the need for research acknowledging such complexity. Belsky's concern about the effect of infant day care on child development includes a review of the research evidence bearing on the issue. He concludes that "extensive nonparental care initiated in the first year is, to a sta-

tistically significant extent, probabilistically associated with insecure attachment, aggression and noncompliance. What remains strikingly unclear at present are the reasons why the associations discerned . . . [in his extensive and thoughtful review of infant day care studies] emerge so persistently in the research literature" (p. 60).

In chapters 4 and 5, Alicia Lieberman and Steven Frankel discuss clinical perspectives in infant day care. Lieberman's sensitive discussion of the subjective experience of the young child in day care suggests that consideration of a competence-based model of infant development versus an anxiety-based model should be of special interest to clinicians. Her integration of these two models illustrates an approach to understanding and improving child care and emphasizes the importance of the clinician as an ally of child and parent in helping them to cope adaptively with the stresses of day care. Frankel underscores the rudimentary status of our knowledge of the long-term effects of day care on the individual. He cites the need for more longitudinal studies and points out that the strength and potential contributions of psychoanalysis in the study of the child's inner world are limited currently by the weakness of its research methods.

Chehrazi calls attention to the experience of parents who must balance working and parenting. Her report of a pilot study in which 20 working mothers were interviewed is followed by a discussion of areas for future research, including part-time versus full-time employment for the mother and the role of the father. Practical suggestions about how to evaluate the quality of child care are included.

Phillips and Whitebook focus on child care providers, beginning with a strong plea for medical and mental health professionals to establish working relationships with day care providers to provide better services for the children who come into health settings. The bulk of this chapter is an excellent and disturbing summary of the multiple factors that work against adequate compensation for child care providers. The authors discuss the compelling need for affordable, high-quality child care, raise concerns about the consequences for children of low standards of care, and present some examples of efforts at solutions.

Patricia Nachman approaches the important role in the lives of young children of child care providers other than their parents. She reports a comparison study in a nursery school setting of extensive observations of two groups of children—one group with their mothers, the other with familiar, constant nonparent caregivers. Nachman examines the roles of the different caretakers in the separation-individuation process and shares her thinking in a stimulating, interesting way.

Barbara Kalmanson's discussion of children's responses to separation focuses on understanding the individual child. She cautions that group data on separation, although providing valuable information, leave many unanswered questions for parents considering day care options for their children. This chapter presents a very useful summary of how parents and day care providers can evaluate the nature, pattern, and magnitude of the child's separation distress, some determinants of the capacity to manage the separation experience, and how parents and day care providers can assist the child.

Pediatric issues in day care are presented by Susan Aronson and Evelyn Oremland. Aronson notes that the United States lacks a surveillance system for infectious diseases and injuries in child care, resulting in a scarcity of data on the health status of children in such settings. She discusses injury control, prevention and management of infectious diseases, and health promotion. Under each topic she summarizes the data avail-

able and discusses corrective action. In addition to the preventive and corrective measures that apply to children's health in general, there is a focus on individual health needs and on the importance of integrating health with other concerns in child care. Oremland's emphasis is on the greater psychological vulnerability of children during illness and the dilemma for parents of deciding when and for how long it is necessary to stay home with their child. Several models for the care of sick children are described. The importance of caregivers' understanding the effect of illness on behavior and the child's need for added support are noted, and helpful, practical suggestions are made.

Robert Kelly's chapter on sexual abuse in day care discusses some of what is known about the reality of sexual abuse in day care in terms of how much and what types of sexual abuse actually occur; the impact on communities, families, and the victims themselves; and how best to cope with the negative impact of sexual abuse. This condensed report of studies and recommendations emphasizes both the impact of sexual abuse and the responsibilities of parents, professional counselors, and the judicial system.

Martin Glasser's chapter on prevention of physical and sexual abuse in day care discusses guidelines for evaluating a prospective center as well as recommendations for prevention and treatment. Clinical vignettes illustrate his major points. He calls attention to variations in a child's experience of trauma related to age, previous history, circumstances of the discovery, and how it is handled by parents, professionals, and the legal system. This is followed by a chapter by Catherine Ayoub, Penelope Grace, and Carolyn Newberger on working with maltreated children and families in day care settings. Emotional abuse and child neglect are discussed, as well as physical and sexual abuse. Here the focus is on how day care programs can alleviate the effects of maltreatment through sensitive, skillful responses to child and family. Thus, day care holds promise as a growth-promoting, therapeutic environment.

In the final chapters, national policy and day care are addressed by Congressman George Miller (D., California), who writes on the expanding federal role in child care, and Carol Stevenson, who discusses child care law and child care advocacy. Miller describes past and current major efforts and some of the major obstacles in the way of developing the child care services so desperately needed. He notes that a policy framework, set in place in the 1980s, requires the backing of fiscal resources, well-trained and compensated child care personnel, and a flexible but firm regulatory structure that ensures safe and nurturing child care environments in every state. Stevenson raises a number of important issues regarding the achievement of a comprehensive system of child care, among them how child care will be regulated; the parents' role; the role of federal, state, and municipal governments; and who will pay and how. The importance of advocates understanding the hard work of finding answers to the questions involved is a central theme.

In summary, Chehrazi has put together a very informative, useful book by a broad array of authors with impressive expertise. Inevitably, there is repetition, but this is no disadvantage, because each chapter can stand alone and the reader is free to choose those topics which address his or her particular interest.

SALLY PROVENCE, M.D.
Branford, Conn.

Attention-Deficit Hyperactivity Disorder: A Handbook for Diagnosis and Treatment, by Russell A. Barkley. New York, Guilford Press, 1990, 747 pp., \$50.00.

Since Barkley's first edition of this book in 1981 (1), much has changed in the diagnosis and treatment of attention-deficit hyperactivity disorder. There has been a flurry of research, changes in diagnostic criteria and philosophies, and the emergence of public awareness about the disorder. This new edition does more than merely update the classic handbook of 1981. It is an entirely new book covering more topics and addressing new issues, not the least of which is that the disorder is different from the one originally described.

The book is divided into three major sections: Nature and Diagnosis, Assessment, and Treatment. The first three chapters provide a historical overview, an elaboration of the epidemiology and phenomenology of attention-deficit hyperactivity disorder, and a review of the conditions that are often comorbid with the disorder. Barkley describes the disorder as a developmental, motivational (not attentional) deficiency with a physiological base and asserts that the inability to adequately regulate behavior by rules and consequences is the hallmark of the disorder. This conceptualization is clearly presented as Barkley's perspective rather than as undisputable fact, a discrimination that is not as easy to make in other sections of the book.

Chapter 4 discusses the developmental course and outcome of children with attention-deficit hyperactivity disorder and the factors that influence prognosis. Chapter 5 describes the parent-child interactions of children with attention-deficit hyperactivity disorder and the psychiatric family histories of these children's biological relatives. Barkley proposes his model for explaining how aggressive behavior develops and is maintained in children with attention-deficit hyperactivity disorder; maternal depression, marital discord, and negative parenting behaviors play major roles. Chapter 6 reviews the diagnostic criteria for attention-deficit hyperactivity disorder as well as for common comorbid disorders. Barkley offers sound advice on supplementing the *DSM-III-R* criteria for attention-deficit hyperactivity disorder with additional criteria to enhance diagnostic specificity (e.g., using cutoff scores from standardized teacher and parent rating scales and lengthening the symptom duration requirement). Barkley's descriptions help the clinician to differentiate the likely etiology and developmental progression of attention-deficit hyperactivity disorder from the other disruptive behavior disorders and from undifferentiated attention-deficit disorder. However, he minimizes the comorbidity of attention-deficit hyperactivity disorder and internalizing disorders on the basis of his own research, in spite of the fact that several of the case histories provided indicate clinically significant elevations in these domains. Given the increasing amount of work on this, one detects a bit of attention deficit in the area. On the other hand, Barkley's discussion of the diagnostic complexities of children who have co-occurring odd thinking, behavior, and affect with seeming attention-deficit hyperactivity disorder is excellent.

The second major section of the book deals with assessment of attention-deficit hyperactivity disorder and begins in chapter 7 with an overview of the biopsychosocial and developmental factors that should be considered in clinical evaluations. Chapter 8 provides a useful "how to" guide on what information should be collected when interviewing the parent, the child, and the teacher. The parent section is supplemented by an interview schedule Barkley developed, which is quite practical and adoptable. A separate section is focused on the

pediatric medical examination, including the medical interview, physical examination, and laboratory tests.

Chapter 9 is an outstanding chapter that explains the role that behavior rating scales should play in the assessment of attention-deficit hyperactivity disorder, provides useful information on the most widely used scales, and recommends particular scales for different types of evaluations. The rating scales are outlined in a highly accessible format that highlights information such as the number of items, factors assessed, availability of reliability, validity, and normative data and where to obtain them.

Chapter 10 provides a brief review of the laboratory measures, neuropsychological tests, and direct observation procedures that have been used to assess children with attention-deficit hyperactivity disorder, discusses their potential clinical utility, and ends with a cautionary assessment of their limitations. Chapter 11 illustrates how to integrate the diverse sources of information obtained in the assessment by presenting six actual clinical cases seen at Barkley's attention-deficit hyperactivity disorder clinic.

Part three of the book addresses treatments of attention-deficit hyperactivity disorder and covers all of the contemporary interventions for the disorder. Many of the chapters are authored or co-authored by colleagues of Barkley's who have developed and implemented programs of their own. Many of the chapters present session-by-session guides on how to conduct the therapy program. These include Barkley's program for counseling and training parents, family systems approaches to parent training (including a family therapy program for adolescents with attention-deficit hyperactivity disorder), behavioral and cognitive-behavioral interventions for the classroom, social skills programs for children with attention-deficit hyperactivity disorder, and assessment and treatment guidelines for adults with the disorder.

Chapter 17 covers medication therapy, and although it is not intended to be a comprehensive or critical review, it presents a clinically useful account of methylphenidate and amphetamine. Controversies (e.g., use of stimulants to treat children with attention-deficit hyperactivity disorder who also have tic disorders) and the practical use of other medications are not covered in the kind of detail that characterizes the other descriptions of treatment.

This second edition of *Attention-Deficit Hyperactivity Disorder* is truly the handbook on the diagnosis and treatment of attention-deficit hyperactivity disorder in the 1990s. It is a readable mix of research findings, personal observations, and clinical implications. Clinicians can find a wealth of useful information that can help them to sharpen their diagnostic skills in identifying attention-deficit hyperactivity disorder, recognize possible comorbid disorders, and broaden their treatment armamentarium. It is a book that addresses a diversity of professionals—psychiatrists, psychologists, pediatricians, social workers, teachers, and school administrators—promoting understanding and hence communication between the disciplines likely to be involved in treating a child or adolescent with attention-deficit hyperactivity disorder. For the practitioner who is likely to evaluate and/or treat individuals with this disorder, it is truly a book worth reading and owning.

JOYCE SPRAFKIN, PH.D.
GABRIELLE A. CARLSON, M.D.
Stony Brook, N.Y.

Childhood Stress, edited by L. Eugene Arnold. New York, John Wiley & Sons, 1990, 573 pp., \$59.95.

Childhood Stress continues the excellent tradition of Wiley's series in child and adolescent mental health. The series presents views on child rearing and child management, child development, child advocacy, and child psychiatry. *Childhood Stress* adds "the most complete and timely coverage" of the major stressors among children and adolescents. Organized into four major sections, the book includes an impressive array of experts who present research findings describing biological aspects of stress, interactions of developmental age with stress, public health aspects of stress (i.e., stressful effects of family and community violence and illness), and assessment-intervention techniques.

I have developed a list of "essential" topics derived from child therapy journals. Arnold covers all but three of these topics and presents additional topics not on my list. Two of the missing topics, childhood stress resulting from living with a terminally ill parent or sibling and stress associated with being the child of a mentally retarded parent, a parent with borderline personality disorder, or a substance-abusing parent, are addressed indirectly. However, given the prevalence of these problems, a more thorough review would have been desirable. Two of the leading stressors for school-aged boys, learning disabilities and hyperactivity, were inadequately addressed.

The references cited come from many fields, with psychiatry predominating. Unfortunately, data from controlled trials are rarely given, and referenced statements are often overgeneralized. For example, no outcome data are presented comparing the effectiveness of different treatments.

Overall, Arnold gives excellent descriptions of childhood stress and meets the goals established for the book and for the series. The copious references will appeal to adventurous readers desiring additional detail. This clearly written book belongs in the library of any professional who is seriously interested in the evaluation, treatment, or management of children. It serves as an excellent reference for the casual reader and a knowledge base for the expert reader.

PSYCHOANALYSIS AND PSYCHOTHERAPY

The XYZ of Psychoanalysis: Epilogue to a Great Beginning, by Harold Feldman. New York, Praeger, 1991, 192 pp., \$39.95.

Dr. Feldman attributes the recent decline in the appeal of psychoanalysis to the rise of narcissism. To establish his thesis he traces the development of psychoanalysis from its hopeful beginning, when the delineation of the role of the unconscious in symptoms promised to solve the mystery of mental illness, to the current situation of resistance to psychoanalytic treatment. Dr. Feldman compares the course of psychoanalysis to that of Marxism, to which he is also partial. Although Marxism and psychoanalysis differ markedly regarding their concepts of the genesis of human problems, they both have faith that man's rationality can solve both his economic and his psychological problems.

Freud was impressed by the impact of unconscious irrational thoughts and beliefs. He hypothesized that if irrational

unconscious thoughts and beliefs could be subjected to conscious rational consideration through the intervention of psychoanalysis, psychopathology would disappear. Sadly, this did not happen; in spite of the analyst's awareness of some issues, symptoms persisted. As a result of continued observation and study in an effort to gain greater understanding of psychic processes, Freud conceptualized the phenomena of transferences, identification, the ego, superego, and narcissism.

Freud's delineation of the origin of the libido involved in these phenomena is murky. Sometimes he designates the id as the reservoir of libido; at other times he points to the ego. Consideration of the ego adumbrated the phenomenon of narcissism, which according to Dr. Feldman focuses on aggression and destructiveness rather than sexual matters. Dr. Feldman distinguishes between primary and secondary narcissism. Primary narcissists are incapable of relating to objects; thus, transference is not established and psychoanalysis cannot proceed, the relationship to the analyst is archaic, patients do not separate themselves from the analyst, and they expect immediate gratification. The psychic structure of secondary narcissists is more mature, but they manifest some primitive narcissistic issues that make treatment difficult.

The focus of individual psychoanalysis on the importance of gratification has fostered narcissism. The narcissistic position has been reinforced by a society in which technical, economic, and political forces favor its development. Individual pleasure is valued over concern for others. In this atmosphere sociopathy, drug abuse, promiscuity, and irresponsibility flourish. Treatment is sought because of displeasure associated with narcissistic deprivation rather than because of conflict engendered by the thoughts or actuality of gratification.

Although Dr. Feldman faults psychoanalysis for encouraging narcissism, he also extols its capacity to counter it. He believes that psychoanalysis can release the uniting, bonding forces of eros which counter the destructive, restrictive forces of thanatos and set humans free to enjoy a richer, fuller, and cooperative life. He parallels this hopeful prediction for the outcome of the psychological distress of individuals with a satisfying outcome for the problems of society when socialism prevails, as he believes it will. Dr. Feldman's conclusions are appealing but not convincing because the evidence on which they are based is limited and the reasoning reductionistic.

REBECCA Z. SOLOMON, PH.D.
Hartford, Conn.

Interpretation and Interaction: Psychoanalysis or Psychotherapy? by Jerome D. Oremland. Hillsdale, N.J., Analytic Press, 1991, 184 pp., \$29.95.

For quite some time now there has been no more important task in the continually expanding field of the psychological therapies than to render our theories of treatment more precisely. Oremland is right on the mark when he notes that the contemporary therapist carries a legacy of "dissatisfaction and disillusionment that inevitably . . . [followed] the nonspecific application of nonspecific theories to overwhelming problems. It is little wonder that the Golden Age of psychoanalysis [after World War II] was to dissolve into the interactive excesses and emphasis on spontaneity, intuition, and absence of training that [has come to] characterize the scene" (p. 5). The formula with which, in Freud's words, we must alloy the "pure gold of psychoanalysis . . . with the copper of . . . suggestion" has yet to be specified, and the complexities of

that task remain daunting. Oremland's contribution to the discussion is to elaborate on the emerging realization that suggestion is embedded in the very heart and fabric of our work. When Freud wrote of the copper of suggestion he was referring to hypnosis, and we continue to think of suggestion in terms of direct and deliberate uses of authority. But the more astute view is that suggestion is ubiquitously laced into all facets of the therapeutic process, sometimes in ways that are quite obvious, more often with exquisite subtlety. This view compels us to restate Freud's metaphor: there is no pure gold of analysis without infusions of copper. Psychoanalysis is distinguished from its derivative psychodynamic therapies only by variations in the proportion of analytic interpretation to interactive suggestion, and the implications of this revision are a good deal more far-reaching than is at first apparent.

Oremland approaches the problem with these central assumptions: 1) All aspects of psychotherapy are interactive, and all interactions create versions of the therapist within the patient. This often affords the patient substantial palliation without understanding. Oremland quotes Ferenczi: "Suggestion [or interaction] . . . is an education in blindness." 2) The single value embedded within the psychoanalytic orientation is that it is better to know than not to know. 3) Interpretation is an interaction, but it is qualitatively different from other interactions in that its aim is solely to add explicit knowledge. 4) Transference interpretations minimize the suggestive effects of the interpretive interaction by making the interaction itself the object of analysis.

So armed, Oremland delineates a triad of the forms of psychotherapy that are informed by psychoanalytic theory: psychoanalysis, psychoanalytically oriented psychotherapy, and interactive psychotherapy. The first two of these therapies are closely similar because each holds that interpretation of all interactional components of the treatment is the central and distinguishing mode of the therapeutic process. This ambitious and exacting emphasis is designed to minimize the effects of suggestion and to vault understanding. It is an enactment of the assumption that better (palliation without understanding) is inevitably the enemy of best (change based on insight). In both psychoanalysis and psychoanalytically oriented psychotherapy the therapist must be ever mindful to identify and resist the ubiquitous pressures from within and without to treat the patient with transferences. Oremland avers that when the latter happens the therapist has sold the patient short or allowed the patient to sell himself or herself short—that is, to be deprived of the opportunity to achieve personality changes of the greatest possible depth, scope, and stability.

There are differences between psychoanalysis and psychoanalytically oriented psychotherapy, but those differences are small in comparison with the extent to which both differ from interactive psychotherapy. In the former the goal is to reduce the suggestive effects of interaction to a minimum by assiduous attention to transference analysis. The opposite is true in interactive therapy. Here the therapist deliberately intensifies aspects of the therapeutic interaction in order to achieve specific goals. Thus, interpretations and other interventions are used as overt and covert directives and suggestions. In interactive psychotherapy, interpretations of the transference are counterproductive insofar as they undermine the intended effect of indirect interactive directives.

Oremland works his way through the major aspects of the psychoanalytic theory of treatment in order to present his clarifications of basic concepts and use them to explicate the distinctions between the different forms of psychotherapy. His clinical examples are rich and clear, and they touch on a raft

of important technical issues and points of theory often misunderstood. For example, neutrality is neither emotional involvement of the therapist nor an affectation of nonresponsiveness. It is the assiduous attempt to keep the field of interaction as undistorted as possible in order to direct the patient's attention to hidden meanings of his or her words and actions in the therapy. In the same vein, on the supposed antithesis of support versus insight in psychotherapy, Oremland says that interpretation is the most supportive of interventions because it adds comprehension to that which is being experienced. Conversely, interactive therapy, not psychoanalysis, is most regressive in its effects on the patient because it engenders unresolved dependency and thus fails to extend the purview of personal responsibility.

If psychoanalytically oriented psychotherapy and psychoanalysis both rely on interpretation as their central mode, how do they differ? The external differences have mostly to do with training of the therapist (analysts are more rigorously trained), the range of patients treated by the method (psychoanalytically oriented psychotherapy applies more broadly), frequency of sessions, and use of the couch (Oremland argues that the use of the couch in psychoanalytically oriented psychotherapy is counterproductive). The essential difference is none of these but lies, rather, in the dominant area of interplay. In psychoanalytically oriented psychotherapy the actualities of the psychotherapeutic interaction—the here-and-now—take precedence, whereas in psychoanalysis the internal soliloquy of the analysand is intensified so that the historical aspects of life experience predominate. However, "in both, a past is located that enriches the present. In both, the future is determined by achieving a fuller, multidimensional understanding of the present" (p. 119). Oremland goes to great lengths to be fair in his comparative evaluation of the different therapies. He allows that psychoanalysis and psychoanalytically oriented psychotherapy are so similar that ultimately there may prove to be little difference between them. But he doubts it, even as he admits that the superiority of psychoanalysis is unproven. Ultimately the question of efficacy "must . . . be considered in the context of the imprecision that colors indications and goals for all the psychotherapies" (p. 122). From the sole vantage point of symptom alleviation, interactive psychotherapy is probably the most widely effective form of treatment, except that in choosing this course the therapist forgoes the promise of the benefits of insight.

Oremland acknowledges his debt to Merton Gill for his own work, for his careful reading of the manuscript that became this book, and then for his acceptance of the offer to write a concluding response, which has been included in the book as a final chapter. In this chapter Gill brings his own seminal thinking to bear on what Oremland has written. In all the major areas they agree, but it is Gill's manner to hone his incisiveness on issues of difference. He leans away from Oremland's triad of therapies toward the idea of a continuum that admixes the balance of the dose and effects of interaction and interpretation. He is less sanguine than Oremland on the question of how far interpretation can be relied on to reduce the interactive effects of interpretation. Gill notes that one cannot *always* interpret the transference and that it is dangerous to believe otherwise because excessive emphasis on transference interpretation is an interaction of major dimensions. In the main, however, Gill lauds Oremland's text and highlights its accomplishments.

Oremland is known through his writing and teaching for his wide range of psychoanalytic scholarship. However, the discoveries about interaction that led to this book appear to have been derived from his own astute clinical observations

rather than his reading of Sullivan or Kohut or the British object relations theorists. He has breached the classical psychoanalytic model of mind as an internally regulated closed system, but he leaves it to Gill to propose that his ideas represent the context of a new paradigm: "It would be an error to read Oremland's monograph as a brief for the employment of the usual analytic technique but at a lesser frequency and sitting up. His major thesis is, rather, that with the recognition of the social nature of the analytic situation the issues of the ubiquity of interaction and the distinction between interaction with and without the analysis of the interaction become central" (p. 142). "The application . . . of these ideas requires a thoroughgoing acceptance of the reality and ubiquity of the interpersonal and interactive nature of the therapeutic situation . . . It also requires a willingness to accept the fact that either we enter into an affective relationship with our patients or we defend ourselves against it. We have no other choice" (p. 161). These truths certainly are not new, but they have been afforded scant attention in the practice and theory of psychoanalysis and its derivative therapies in the United States. That deficiency is in the process of being corrected, and in no small measure the credit goes to thinkers like Oremland and original works such as this one.

JUSTIN SIMON, M.D.

The Use of the Self: Countertransference and Communication in the Analytic Situation, by Theodore J. Jacobs. Madison, Conn., International Universities Press, 1991, 238 pp., \$27.50.

It is not infrequent that a book with a title referring to psychoanalytic psychiatry is relegated to analytic institutes or the back shelves of science libraries. Theodore Jacobs' most recent book, however, is one that I hope will not suffer the same fate. In it are many ideas and concepts that are of use to psychiatrists who do psychotherapy of all types and are applicable to an audience of general psychiatrists as well.

Much of the book consists of Jacobs' reflections on his experiences with patients in analysis. These are used as clinical illustrations of aspects of transference and countertransference discussed in the book. In an interesting twist of parallel processing, Jacobs' willingness to write about his personal reactions to patients and to share his own experiences invites the reader to reflect on his or her own interactions with patients. This self-disclosing and interactional style of writing serves to convey one of the main concepts in the book. Reading, like psychotherapy, is transformed into an interpersonal phenomenon. The reader/psychotherapist is influenced by the communication of the writer/patient rather than simply acting as an objective and nonparticipant observer. The evocation of thoughts and memories from the reader as a result of Jacobs' own self-disclosure mirrors the manner in which we are influenced during the course of our interactions with patients.

A corollary to the interpersonal nature of therapy is that transference phenomena must develop in the context of the patient-therapist interpersonal relationship. Rather than the "traditional" view of transference as a purely intrapsychic phenomenon, Jacobs reconceptualizes transference as a product of each unique patient-therapist combination, in which each member of the dyad contributes important past and present experiences and associations. The therapist's ability to understand his or her own contributions to this dynamic re-

lationship is paramount in fostering the emergence of a more complete understanding of the patient. Jacobs argues quite convincingly that awareness of all aspects of patient-therapist communication, particularly nonverbal communication, is essential to furthering understanding. According to Jacobs' model, therapists' recognition and awareness of such things as their own physiological responses and mental imagery during sessions can be used to facilitate an understanding of the patient.

In later chapters, Jacobs describes some ways in which therapists can collude with patients in concealing important information or emotions. This often results from therapists' resistance to examining their countertransference responses and ultimately hinders the conduct of psychoanalysis. One could well make the case that resistances to recognizing countertransference responses to patients hinder the delivery of therapy of any kind. In extreme cases, a therapist's ignorance about his or her contributions to the therapeutic relationship can lead to repression of emotional reactions on the part of the therapist that are nonetheless evident to the patient. These become secrets shared by the patient and therapist. To illustrate this point, Jacobs describes a case in which one of his patients discovered some information about a painful personal loss Jacobs had recently experienced. Through several sessions, Jacobs ignored the patient's hints about the possession of this knowledge. It was only after coming to what Jacobs describes as a personal understanding of his own grief reaction that he was able to hear these messages from his patient and to analyze the ways in which these secretive communications from the patient had been reflected in the therapeutic relationship.

It is unfortunate that Jacobs' book is aimed at such a narrow audience. The ability to understand our responses to patients and to attend to all forms of communication between ourselves and our patients are skills that should be developed in all psychiatrists. Although the examples used by Jacobs are from analytic cases, they are nevertheless applicable to all professionals who interact with patients. An understanding of our limitations and very human reactions to patients and the way they ultimately affect our interactions with patients would be well advised in all practitioners of medicine, particularly when the profession is being taken to task for its lack of empathy. This book should serve as a reminder to both clinician/readers and mentor/authors—to clinicians who would do well to broaden their understanding of themselves and their patients and to mentors who would do well to encourage us to do so.

SCOTT STUART, M.D.
Iowa City, Iowa

Conflict and Compromise: Therapeutic Implications, edited by Scott Dowling. Madison, Conn., International Universities Press, 1991, 248 pp., \$32.50.

This is a curious book, one that begins to make any kind of sense only after reading the entire text and getting the gist of its political agenda. It starts off, incomprehensibly, with three theoretical papers that have nothing to add to what has been known for years now among orthodox psychoanalytic theorists. It is difficult to understand why this monograph in the Workshop Series of the American Psychoanalytic Association should begin with a set of stale theories. We are told, for example, that "the history of the patient's neurotic conflicts is

reenacted in" the analytic setting, as if no one has ever challenged the idea that psychoanalysis succeeds in becoming in reality a laboratory-like situation. Numerous modern workers have pointed out the multiple tilts introduced by so-called classical analysis in the relationship that develops between therapist and patient.

When clinical issues are raised in the first three chapters, they are barren of reports of sensitivity on the part of therapists to the role of their countertransference reactions toward patients. There is one illustration of a clarinet-playing patient that is designed to illustrate the concept of sublimation, but it reads like a travesty of Freudian thinking dating from before World War I; the author reduces the musical accomplishment to a series of sexual conflicts without an adequate awareness that human achievements defy such belittling.

Chapters 4, 5, and 6 deal with case material, and they are as interesting as all reports of clinical encounters are bound to be. As with the early chapters, however, I felt increasingly uneasy about a lack of adequate material about what was most idiosyncratic about the therapists themselves, except perhaps that they felt secure in safely practicing a well-established science without need of any special justification.

The remaining half of the book is made up of "discussions," starting off with a piece by Charles Brenner, a leading orthodox psychoanalytic theoretician. After a second, unilluminating chapter, there follow two chapters that help explain, I think, the purpose of *Conflict and Compromise*. Here we find a section written by a Kleinian analyst and then a piece composed by a self psychologist. Notice that these appear in the "discussions" rather than in chapters equal to those which begin the book. I found the self psychology chapter potentially arresting, but it looks like it will be another generation until a Jungian gets allowed into the fold at such orthodox "workshops." One of the early theorists in the text tells us that "numerous psychoanalytic contributors have carefully built up this new knowledge during the past fifty years without much fanfare or polemic insistence on forming new schools" without seeming to be aware how smug such a sentiment sounds.

Once the Kleinian and the Kohutian have had their say, the book concludes with the responses of the original authors. I found a tone of weary superiority over innovative ideas, combined with self-congratulation about what has already been accomplished. The Kleinian and the Kohutian are very well behaved, and there is no sound here of the thunder of battle, or even the life of the mind.

Psychoanalysis cannot survive, I think, without a great deal more openness. *Conflict and Compromise* does not read like a workshop where people are genuinely testing out new ideas or groping for new formulations. Parts of it sound like a funeral dirge; and if the point of the exercise was to demonstrate so-called toleration toward a Kleinian and a Kohutian, then I think that the illusion of genuine debate can do damage in reinforcing the prejudices and preconceptions of the old establishment.

A sound book might have given substantial conceptual standing to viewpoints other than the ones expressed in the bulk of the text. As it is, *Conflict and Compromise* will not change the way anyone thinks, although it may get added (surely unread) to the bookshelves of orthodox psychoanalysts.

PSYCHIATRIC PRACTICE

Confidentiality Versus the Duty to Protect: Foreseeable Harm in the Practice of Psychiatry, edited by James C. Beck, M.D., Ph.D. Washington, D.C.; American Psychiatric Press, 1990, 212 pp., \$25.00.

In the past 20 years the number of reporting duties imposed on psychiatrists has increased dramatically. In the past, exceptions to confidentiality were mandated primarily for the benefit of the patient. A therapist's duty was essentially only to the patient. Within general medicine, physicians were required to report patients with epilepsy who operate vehicles, patients with gunshot or knife wounds, and those with contagious diseases. These exceptions had few effects on the practice of psychiatry.

Today, psychiatrists are obliged to report or otherwise protect against danger posed by their patients. Along with other physicians, they are obliged to report abuse of children and the elderly, and, as a condition of payment for their services, they must report information to third-party payers.

Since the well-publicized case of *Tarasoff* (1), there have been more than 70 published cases in which psychiatrists and other psychotherapists as well as hospitals and other health care facilities have been named as defendants in suits alleging breach of the duty to warn or protect. Troubled by the prospect of liability, state psychiatric societies have pushed for legislation spelling out clearly their duty under the law and restricting the duty to a warning. Legislation to this effect has been adopted in a number of states.

The specter of AIDS-related *Tarasoff* suits now worries many psychiatrists. Sexual partners of individuals with AIDS are foreseeably endangered. Does this create a legal duty for the psychotherapist of an AIDS patient and, if so, how does the therapist fulfill it?

In dealing with children and families, therapists are confronted with child abuse reporting laws. How do therapists treat a pedophile when they are obliged to report? How do they treat a parent who abuses a child when they are obliged to report?

How do therapists treat patients with antisocial personality disorder when, by definition, they pose a problem to society? The difficulty in protecting third parties from the violence of an antisocial patient is complicated by the fact that one of the standard ways of carrying out an assumed duty to protect potential victims is to attempt civil commitment, but in most jurisdictions, a person who is not actually harming someone does not fit the statutory definition of mental illness.

The past decade has witnessed greater public attention to the hazards arising out of the use of motor vehicles. Alcohol or drug use has compounded the danger. Some state statutes require that physicians report patients with conditions that may affect their ability to drive. Some cases, modeled on the *Tarasoff* decision, speak to an obligation to protect the public that is not based on statute.

Sexual activity between therapists and patients has attracted increasing attention. Three states have enacted statutes requiring a therapist to report a former therapist accused by a patient of sexual exploitation to the appropriate licensing authority or to inform and enable the patient to report.

This book covers these and other issues. Dr. Beck opens the book with two overview chapters, followed by Robert I. Simon's chapter on the duty to protect in private practice, Kimberly White and Beck's on the duty to protect in emergency psychiatry, Bruce Gage's on the duty to protect in inpatient

psychiatry, Richard Barnum's on managing risk and confidentiality in clinical encounters with children and families, Spencer Eth and Gregory B. Leong's on therapist sexual misconduct, Kenneth Appelbaum and Paul S. Appelbaum's on the patient with HIV, Stephen J. Bartels and Robert E. Drake's on the dual-diagnosis patient, Landy F. Sparr and David J. Drummond's on posttraumatic stress disorder and the duty to protect, Joseph B. Layde's on the antisocial patient, and Sally L. Godard and Joseph D. Bloom's on driving, mental illness, and the duty to protect.

Eth and Leong suggest cautioning patients that the therapeutic relationship is not sacrosanct, thus conveying the essence of a *Miranda*-like warning. Simon suggests documentation on the assessment of violence.

The value of warnings remains to be proven. In *Tarasoff*, when the therapist notified the police, the patient left treatment and subsequently carried out his threat. In Detroit, when the police are informed that a patient poses a danger, the usual response is, "We're busy with dead bodies. We can't be bothered with threats."

Haunted by fear of a lawsuit, therapists lose the ability to think clearly and to rely on their clinical judgment. This book may prove helpful, but good clinical judgment remains the best guide for the clinician. In most circumstances, the actions the therapist may take to protect others are the same actions that will be of clinical benefit to the patient. As a basic principle, it will almost always be in the patient's interest to be prevented from harming other people. In any event, the odds of a psychiatrist being sued for breach of the duty to protect, going to trial, and being found liable are 5,800 to 1 in any one year.

The book reads easily, has little overlap, reflecting good editing, but lacks an index.

DISEASES OF THE ELDERLY

Subcortical Dementia, edited by Jeffrey L. Cummings. New York, Oxford University Press, 1990, 267 pp., \$45.00.

For a new disease to be recognized, its signs, symptoms, and course must be distinguished from traditional formulations of similar presenting conditions. Such is the case made by the authors of this book for subcortical dementia, a syndrome of cognitive dysfunction characterized by defective recall, poor abstraction, and loss of initiative and associated most commonly with changes in mood and motor behavior as well. Aphasias, apraxias, or agnosias are generally absent, in contrast to cortical dementia. Despite strong support from recent research elaborating cognitive functions of the striatum, the concept of subcortical dementia is not without controversy. What purpose is served creating yet another, somewhat artificial dichotomy? Is it legitimate or useful to describe subcortical dementias as reversible and cortical syndrome as irreversible? Most dementing diseases and lesions involve circuits having both cortical and subcortical components, making as-

essment of the relative contributions of each anatomical area problematic.

This book is the first coordinated response to such concerns, written by true believers who present a scholarly defense of the history of subcortical dementia, its neurochemistry and anatomy, and its characteristic profile in Huntington's and Parkinson's diseases, progressive supranuclear palsy, multiple sclerosis, and AIDS dementia complex. Of greatest interest to psychiatrists are two chapters masterfully integrating neuropsychological and physiological changes in depression and in normal aging from a subcortical perspective. Notably absent, however, is a chapter that summarizes the literature on tardive dysmetria and the adverse cognitive sequelae of long-term neuroleptic use, a topic seemingly quite germane to subcortical dysfunction. Clinical and management implications of the diagnosis of subcortical dementia are in general subordinated to more theoretical and phenomenologic observations.

As might be expected from a syndrome still being defined, tautologies and contradictions emerge. Aphasia, excluded by most authors, is put forth as a central feature in a chapter reviewing focal subcortical lesions. In contrast to patients with Huntington's disease, patients with Korsakoff's disease are described at one point in the book as benefiting from procedures that increase the opportunity for encoding, while in another chapter and table, encoding enrichment is viewed as unhelpful in cortical and beneficial in subcortical dementia. The concept of perseveration is also variously defined. The methodology of studies unsupportive of the dichotomy is often critiqued but positive reports are embraced without comparable scrutiny. Most of the studies reviewed on cognitive change in AIDS dementia fail to control for adverse effects of medication or concomitant depression, and few of the reports comparing cortical and subcortical dementias account for possible differences in severity, stage of illness, or treatment differences. However, in academia, as in football, the best defense is a good offense, and these authors move down the field convincingly. The writing is concise, the graphics are of high quality, and the book is well referenced and edited. There is joy, too, in encountering an idea still so fresh that its complete history and literature can be definitively examined in a 267-page book.

VICTOR I. REUS, M.D.
San Francisco, Calif.

Family Involvement in Treatment of the Frail Elderly, edited by Marion Zucker Goldstein, M.D. Washington, D.C., American Psychiatric Press, 1989, 240 pp., \$28.50.

This book is number nine in the Clinical Practice Series of the American Psychiatric Press, which, according to series editor Judith Gold, attempts to "provide current, factual, and theoretical material of interest to the clinician working outside of a hospital setting" (p. xi). Unfortunately, this promise is not fulfilled.

In her introduction, Dr. Goldstein defines the frail elderly as "those who cannot live or travel independently, cannot maintain interest in self and others, and require a so-called 'therapeutic environment' in the community or institutional setting" (p. xv).

She goes on to note that "an effort has been made to leave it up to the practitioner/teacher to translate into practical use the theoretical and informative material presented in this volume" (p. xvii).

Chapter 1, "Parent Care," by the editor, is the most interesting in the book, principally because of Dr. Goldstein's gripping account of her attempts to deal with her demented mother, first in a "personal care home," and later in a skilled nursing facility. As the baby boom population ages, one in three families in the United States will have a frail elderly member to care for.

In chapter 2, "Spouses as Caregivers: Stresses and Interventions," Steven Zarit, Richard Birkel, and Eileen Malonebeach inform us that 36% of all caregivers are spouses (23% wives and 13% husbands). We learn what caregivers must cope with, including activities of daily living (helping the patient bathe, toilet, and dress), "positive" symptoms (wandering, agitation, and forgetfulness manifesting itself in the interminable repetition of questions), and "negative" symptoms (the amount of time needed for household and family activities formerly performed by the patient). We learn the mediators of care demands (the family's financial resources, amount of substitute caregiving, and amount of emotional support available) and the problems associated with caregiving (decreased physical and emotional well-being, financial problems, and social isolation).

The empirical findings on caregiving by spouses are slender. One finding is that spouses are more reluctant than children to institutionalize a patient with dementia. Using a behavioral model, the authors briefly discuss interventions such as providing the family with information about the disease, helping develop more effective management strategies, arranging substitute caregiving, and recommending legal and financial counseling.

In chapter 3 Kenneth Sakauye deals with "Ethnic Variations in Family Support of the Frail Elderly." Once again, there is little empirical research to draw on. Approximately 10% of the population over 65 is nonwhite. Multi-infarct dementia is the major cause of dementia in blacks and Asians, whereas Alzheimer's disease is the major cause in whites. The onset of chronic illness and disability frequently occurs at a younger age in nonwhites, but suicide rates and rates of institutionalization are lower in nonwhites.

In chapter 4, "Mutual Support Groups for Families of Alzheimer's Disease Patients," Martha Bell recommends self-help support groups as effective vehicles to assist families. She discusses guidelines for the formation of a support group, including frequency (once a month on a weekday evening), length (two hours), those most likely to attend (primary caretakers or an adult child), and possible leaders. She provides a 28-page appendix listing the local chapters of the Alzheimer's Disease Association and the state commissions on aging.

Chapter 5, "Economic Supports for Family Caregivers of the Elderly," by David Beigel et al., consists largely of the results of a survey of state units on aging. Once again there is a state by state listing of the meager supports available, including tax credits and deductions and direct payment programs.

In the final chapter, "Medical Students' Attitudes Toward the Care of the Frail Elderly and Their Families," Leah Dickstein et al. note that clinicians are prejudiced against the elderly, seeing them as more emotionally ill, inactive, dependent, and socially undesirable. This chapter is mostly devoted to the results of a study in which medical students completed a questionnaire before and after their psychiatry clerkship. The results demonstrated that the students' attitudes to the elderly became more positive after the clerkship.

This book will be of interest to psychiatrists preparing for the geriatric psychiatry examination. The information it pre-

sents is insufficiently detailed to be of much practical use to the psychiatric clinician in helping families manage their frail elderly.

JOHN C. RAISS, M.D.
Beverly Hills, Calif.

AIDS

Behavioral Aspects of AIDS, edited by David G. Ostrow. New York, Plenum, 1990, 430 pp., \$55.00.

When the institutes of the Alcohol, Drug Abuse, and Mental Health Administration first announced plans to fund research studies about HIV infection and AIDS, many critics argued that the money would be wasted. Give the money to the virologists and immunologists, they argued, and soon we will know everything about what causes AIDS, how to treat HIV infection, and how to make a vaccine.

The AIDS epidemic is now 10 years old. An enormous amount has been learned about the virus that causes the disease, but sadly our treatment efforts are mostly palliative and, at least at this writing, we do not yet have a vaccine. Zidovudine is the only drug specifically developed and marketed to treat HIV so far, and it clearly does not cure HIV infection. The most successful medical interventions for people infected with HIV have been drugs that control the secondary, opportunistic infections. Most of these, like pentamidine for the treatment of pneumocystis pneumonia, were discovered before the outbreak of HIV.

At this time, the only way to prevent HIV infection is behavioral change; therefore, the research that has gone into understanding how that can be accomplished is absolutely critical in fighting HIV infection. This book, consequently, contains some of the most important information a scientist, clinician, or concerned citizen interested in HIV infection and AIDS could possibly read.

This book is encyclopedic. It is organized into four main sections. First is a section called AIDS: Contributions of the Behavioral Sciences; this section includes discussions of psychiatric and psychological aspects of AIDS and other sexually transmitted diseases. The second section is Prevention: HIV Risk Reduction. The third is Neuropsychiatric Aspects of AIDS, and the fourth is Health Care Delivery Issues.

The book has many strengths. It is so comprehensive that most readers will want to pick and choose among chapters. Except for the omission of the basic science of retroviral infection of nervous tissue, it is hard to think of any topic related to behavioral and CNS aspects of AIDS that is not here. The chapters deal sensitively with the particular needs and issues of gay people, minorities, and women. They often paint a dramatic and moving picture of life with AIDS for both victims and caregivers. And they contain information of diverse kinds, from the results of brain imaging studies to lists of organizations in U.S. cities that provide help for patients.

The book begins with a beautifully written chapter by Daniel Defert called "A New Social Reformer: The Patient." Defert shows great compassion for health care workers who must change fundamental attitudes because of the epidemic and convinces us that patients with AIDS will reform medical practice worldwide. Robb W. Johnson, David G. Ostrow, and Jill Joseph provide a comprehensive review of "Educational Strategies for Prevention of Sexual Transmission of HIV" and remind us that merely knowing how AIDS is transmitted is

entirely inadequate for fostering change of high-risk behavior. The authors note, "Education that aims solely to increase knowledge would appear to be limited in its ability to induce and maintain alterations in behavior" (p. 45).

One of the most compelling chapters is by Ritch C. Savin-Williams and Rand E. Lenhart. Titled "AIDS Prevention Among Gay and Lesbian Youth," the chapter is outstanding in its sensitivity and clear recommendations for better treatment of gay youngsters. The chapter is full of information on the psychosocial development of gay and lesbian youth and offers practical guidelines for health care personnel who interact with them. A chapter by Dooley Worth on "Women at High Risk of HIV Infection" is well written and highlights how much more we need to know about the specific problems and characteristics of women with AIDS. Also commendable are chapters on "Intravenous Drug Use and AIDS," "Diagnosis and Treatment of Neurologic Disorders in AIDS and Other Sexually Transmitted Diseases," "HIV Disease: Brain-Behavior Relationships," and "Adjuvant Treatment of HIV Dementia With Psychostimulants."

The book is not perfect, of course. Too many of the authors rely on anecdote and personal observation, and references are often to obscure, nonrefereed journals. A chapter on management of neuropsychiatric disorders in HIV-positive patients states that "anxiety disorders are especially prevalent . . . mood disorders can include major depression, suicide, and affective psychoses" (p. 174). The reference for this is a general review, leaving the reader wondering if there are any data to support these claims. In fact, recent experimental evidence suggests that psychiatric disorders may be no more common among patients with HIV infection than in the general population.

A chapter on diagnosis and treatment of acute psychological problems in HIV-infected patients persistently insists that panic attacks occur in HIV infection, although again there are data against this. This chapter also claims that "the additional propensity of some antidepressants to induce leukopenia must also be borne in mind" (p. 199), again without presenting any evidence for a side effect of antidepressants with which I am

not familiar. The statement in another chapter that "in our experience, neurologic deficits and psychiatric symptoms usually coexist" (p. 272) is interesting but, once again, unsupported by experimental evidence. A chapter on "Mental Health Services Delivery Issues" by James J. Strain and George Fulop contains very interesting information on instruments for assessment of cognitive function in patients but also takes annoying and gratuitous shots at *DSM-III-R* that are irrelevant and should have been edited out.

There are the usual problems with redundancy. Half a dozen chapters review the fact that HIV infects the CNS and causes neuropsychiatric complications. There is also a lack of careful editing, with a few too many grammatical errors and misspellings; these fine authors deserved better from the publisher.

But all of these are relatively minor quibbles. The way to correct the few problems in this excellent book is obvious. Dr. Ostrow should be urged to begin a second edition immediately. This could include some of the data on prevalence of psychiatric disorders in HIV infection and on the use of psychoactive medications in patients with AIDS that became available after the book went to press.

While we wait for the second edition, there is plenty to be informed and moved by in this first edition. Ostrow, J. Hampton Atkinson III, and Igor Grant note that "in the early days of AIDS and treatment, psychiatrists, psychologists, and other mental health caregivers came on the scene mostly as an afterthought, providing support or understanding to victims of a catastrophic illness or to manage the occasional behavioral or neuropsychiatric complications. The studies reviewed here and our ongoing work indicate a true primary role of psychiatry in the diagnosis and treatment of these patients" (p. 183). For those interested in accepting that primary role, this book is a very good place to start.

Letters to the Editor

Addition of Fluoxetine to Clozapine

SIR: Fluoxetine has been added to typical neuroleptics for treatment-resistant symptoms in schizophrenia (1, 2). We report a case of adding fluoxetine to clozapine for a schizophrenic patient with obsessive symptoms. The only other reported concomitant use of neuroleptics and fluoxetine involved a nonschizophrenic patient who had a grand mal seizure while taking clozapine, clomipramine, and 100 mg/day or more of fluoxetine (3).

Mr. A was a 39-year-old man with a diagnosis of chronic paranoid schizophrenia beginning at age 20 when he felt people were talking about him. Symptoms of agitation, persecutory delusions, and thought broadcasting led to several hospitalizations. Auditory hallucinations, "people talking together," became prominent 10 years after onset. Past treatments included trials of chlorpromazine, fluphenazine, and haloperidol; imipramine and trazodone were tried adjunctively; and a course of ECT had been given. Although improving from exacerbations of his symptoms, he continued to have persecutory suspiciousness, ideas of reference, social withdrawal, and anxiety.

Mr. A was placed on clozapine, and his dosage gradually increased to 800 mg/day. Over the next year he showed improvement in symptoms but continued to be anxious, misinterpreted talking and laughing as directed at himself, and mainly complained of repetitive cursing thoughts. While not a complaint before, cursing thoughts had occurred earlier during a drug withdrawal exacerbation. This symptom was experienced as an intrusive and unwanted product of his own mind, and he fought it with repetitive, idiosyncratic prayers and by trying to think opposite thoughts. The obsessive quality of this symptom led us to consider a trial of fluoxetine, which was started at 20 mg every other day and increased over 5 months to 80 mg/day. A reduction to 60 mg/day was necessary due to tremor and nervousness.

Within the first 4 months, episodes of intrusive cursing thoughts were reduced in frequency and intensity. Mr. A found it easier to suppress these thoughts when they started. Eye contact and rapport with staff improved and anxiety was lessened. He also felt a subjective improvement in mood and energy. Referential ideation occurred intermittently but less frequently, and he continued to have anxiety interacting with strangers. The patient noted how his mind had cleared. Family and nonstaff health professionals remarked on Mr. A's improvement.

Adding fluoxetine to clozapine in the treatment of schizophrenia may be potentially useful. Fluoxetine may raise clozapine levels, as seen with haloperidol (4), and aid improvement. However, fluoxetine may potentiate akathisia and extrapyramidal side effects (5), absent with clozapine, resulting in treatment failure. The potential antagonism between a serotonin (5-HT) reuptake inhibitor and a 5-HT₂ receptor blocker presented no clinical dilemma.

Polyserositis Associated With Clozapine Treatment

SIR: Recently there has been much written concerning the side effects of clozapine (1-3). Polyserositis associated with clozapine therapy has not been reported in the literature. We present a patient who developed both pleural and pericardial effusions during a trial of clozapine. The effusions resolved when the drug was withdrawn and developed again when clozapine treatment was restarted. Our experience with this patient suggests that polyserositis may be a complication of clozapine therapy.

Ms. A was a 39-year-old woman with a diagnosis of chronic schizophrenia. She had a traumatic brain injury at age 16 and a subsequent grand mal seizure disorder. She had no prior history of respiratory or rheumatological disease. She had been treated over 17 years for auditory hallucinations and disorganized behaviors with chlorpromazine and fluphenazine hydrochloride with some limited success but developed significant extrapyramidal side effects. She was therefore hospitalized for a supervised trial of clozapine. An initial dose of 25 mg/day was increased by 25 mg every other day. On day 9 of treatment, at a dose of 150 mg/day, she developed a temperature of 101.4 °F (rectal) without any sign of infection. It was believed that the elevated temperature was secondary to a drug fever associated with clozapine. On day 16, at a dose of 350 mg/day, the patient continued to have intermittent temperature elevations to 102 °F (rectal), and a chest X-ray revealed bilateral pleural effusions, greater on the left than the right. Clozapine was discontinued at this time. Analysis of the pleural fluid revealed an exudate (protein=3.0 g/dl, LDH=614 IU/liter) with no organisms identified on gram stain, acid fast stain, and aerobic and anaerobic cultures. The pleural fluid cell block showed numerous neutrophils and reactive mesothelial cells. The patient was reactive to an anergy panel but nonreactive to purified protein derivative. HIV testing was

negative, and amylase was not elevated. A rheumatologic work-up, which included antinuclear antibodies, erythrocyte sedimentation rate, and rheumatoid factors, was non-diagnostic. A repeat chest X-ray 9 days after discontinuation of clozapine treatment revealed complete resolution of the pleural effusions. At this time clozapine treatment was restarted at a dose of 25 mg/day and increased 25 mg per day.

On day 6 of the second clozapine trial the patient again developed an elevated temperature to 102.4 °F (rectal), and chest X-ray revealed recurrence of the left pleural effusion. Clozapine was discontinued at this time, and within 7 days radiologic exam showed the pleural effusion had resolved. An echocardiogram at the time of the recurrence of the pleural effusion showed a moderate pericardial effusion with no compromise of cardiac function. A repeat echocardiogram 2 weeks after the discontinuation of clozapine revealed complete resolution of the pericardial effusion.

Ms. A was also taking valproic acid and fluoxetine during the clozapine trial. The patient had been taking both of these medications for several years without any adverse effects. She continued taking these medications throughout the trial and after the clozapine was discontinued and the pleural and pericardial effusions resolved. Given these facts, it is unlikely that either of these medications, alone or together, caused the effusions.

A pharmaceutical corporation has previously received the following reports of adverse reactions associated with clozapine: one case of polyserositis, one case of pleural effusion, and separate cases of pericardial effusion and pleural effusion, both with associated pericarditis. In all cases a direct link to clozapine could not be established but in each case the effusions resolved with discontinuation of the clozapine (personal communication).

Although we are unable to say with certainty that the pleural and pericardial effusions were a direct result of clozapine therapy, the lack of evidence of other etiologies, the temporal relationship of the development and resolution of the effusions with the initiation and discontinuation of clozapine, and previously reported cases to the drug manufacturer suggest this medication was the cause of polyserositis in our patient.

Disulfiram Toxicity and Catatonia in a Forensic Outpatient

SIR: Although disulfiram has been widely used by patients without detriment to their physical or mental health, incidents of disulfiram toxicity have been extensively reported in the literature (1). It is also well documented that catatonic behavior can and does occur without the presence of psychoses (2).

Several earlier single case studies have linked the occurrence of nonpsychotic catatonic behavior to disulfiram toxicity (3). It appears that certain individuals may be predisposed to suffer disulfiram-induced catatonic symptoms.

We report a case of a forensic outpatient with a major mental illness who was treated with disulfiram in addition to antipsychotic medications. As the duration of disulfiram treatment lengthened, the patient became increasingly catatonic and eventually required hospitalization. It should be noted that the patient had no prior history of catatonic symptoms secondary to his schizophrenic illness.

Mr. A was a 56-year-old man with a history of paranoid schizophrenia and alcohol abuse who was found not guilty by reason of insanity and recently discharged from a state mental hospital. As a condition of release into the community (4), he was ordered by the local superior court to begin a medication regimen of disulfiram, 250 mg daily, in addition to his trifluoperazine, 10 mg/day, and trazodone, 50 mg/day. Approximately 3 weeks after beginning the disulfiram, Mr. A was taken to the emergency room of a local hospital after exhibiting shortness of breath, confusion, memory loss, and disorientation. These symptoms had escalated during a 12-day period following an episode of syncope. The results of an initial CT scan indicated no abnormalities, and the patient was admitted to the neurology ward in the hospital for further testing. He was thought to suffer from some toxic metabolic abnormality. Infectious process and drug screen both proved negative. An EEG indicated moderate, generalized, nonspecific abnormalities. No epileptiform discharges or focal abnormalities were observed, though prominent theta activity was noted. The lumbar puncture produced a clear, colorless fluid. ECG results indicated a normal sinus rhythm.

A psychiatric consultation was obtained. Mr. A was believed to be suffering from delirium with underlying schizophrenia. All psychiatric medications, disulfiram, trifluoperazine, and trazodone, were discontinued. Initially he demonstrated a marked decrease in reactivity to the environment. He sat nearly motionless, and his affect was flat. He was oriented only to person, with memory 0/5 after 5 minutes, and able to follow only simple one-step commands. With the cessation of all medication, he gradually improved. At the time of discharge, 12 days following admission, he was again normally responsive to his environment, alert, communicative, oriented, and able to follow complex commands. He demonstrated no memory impairment and had a full range of affect. He was ambulatory and able to care for himself. It is believed Mr. A suffered from disulfiram toxicity which accounted for the change in his mental status. He resumed trifluoperazine, 5 mg/day, as an outpatient and has been functioning well, without further incidents.

Cases such as this lend support to the argument that catatonia should be considered a separate diagnosis in *DSM-IV* (5), distinct from schizophrenia. Addition of such a diagnosis would alert the physician to the diverse etiologies of catatonia and guard against diagnostic confusion and inappropriate treatment as a symptom or subtype of schizophrenia when it is unrelated to this major mental disorder.

Protecting Patients From Clinician-Patient Sexual Contact

SIR: A recent court decision, *Bash v Board of Medical Practice* (1), reflects an important, and in our opinion, alarming trend in the current debate as to what is the most appropriate preventive measure to protect patients from the harms that accompany clinician-patient sexual contact. The decision in question affirmed a medical board's decision to require, in the conditions for reinstatement of a psychiatrist found guilty of exploiting the physician-patient relationship for his own sexual gratification, a permanent restriction prohibiting him to treat females.

While such categorical restrictions might be appropriate in other contexts, such as the treatment of patients with pedophilia, they do little to address the underlying failures of self and clinical management that characterize patient-clinician sexual contact.

In our forensic psychiatric experience, as well as in the experience of our colleagues, cases where such contact has occurred are also characterized by other serious breeches of the standard of care, such as the failure to focus on the development of a therapeutic alliance essential for treatment to proceed. Until the offending clinician demonstrates that such failures have been remedied, we are concerned that the clinician who cannot be considered as competent to treat women should be considered as competent to treat men. Moreover, we are concerned that such categorical half-way measures perpetuate the traditional stereotypes of women as "the weaker sex," stereotypes that in themselves have all too often limited the scope of therapeutic efficacy. A professional who subscribes to the stereotype of women as either objects to be exploited or protected is seriously impaired in treating both women and men.

Major Depression or Alcohol-Induced Organic Affective Syndrome?

SIR: Capt. John R. Cusack's review of William Styron's *Darkness Visible: A Memoir of Madness* (1) included the suggestion that the book "should be requisite in the core curriculum for psychiatric residents." Styron's account of his struggle with depression was also widely acclaimed in the popular press for its artful description of depressive symptoms. While *Darkness Visible* (2) may be compelling reading, critics in gen-

eral and Capt. Cusack in particular have unfortunately not addressed the critical point side-stepped by Styron himself, which is the link between previous alcohol dependence and depression. Styron reported a history of alcohol abuse over 40 years; he abruptly stopped drinking 6 months before his hospitalization at age 60. Styron's formulation does not include the possibility that his alcoholism had engendered his depression; he discounts this possibility ("it had never truly depressed me during my drinking career, acting instead as a shield against anxiety"), proposing that the absence of alcohol made him "emotionally naked, vulnerable [to depression] as I had never been before." He concluded, "I shall never learn what 'caused' my depression, as no one will ever learn about their own."

In fact, recent research has attempted to characterize the specific pattern of depressive illness seen in alcoholics after periods of observed sobriety. Dackis et al. (3) concluded in their study of 49 severely depressed alcoholics evaluated after a period of documented sobriety that, given the atypical pattern of recovery from severe depression, many of the alcoholics probably "did not, in fact, have major depression. Instead they may have had alcohol-induced, organic affective syndromes." Cook et al. (4) studied 58 male inpatients over 55 years old with nonbipolar depression, of whom 16 had a history of alcoholism. Results tentatively supported the concept of subtyping elderly depressed patients in terms of past history of alcoholism. They concluded that "the pattern of their illness tends to be more chronic" compared with depressed elderly men without a history of alcoholism, suggesting an etiologically distinct pattern of depression or the possibility that "alcohol exposure induces organic changes of the central nervous system which persist, and predict poor response to treatment."

If *Darkness Visible* were made requisite reading, as suggested, then consideration of these and other investigations that systematically examine the link between alcoholism and depression should be required as well.

RICHARD HERSH, M.D.
Chicago, Ill.

Capt. Cusack Replies

SIR: Dr. Hersh's comments are appreciated. His remarks blend a book review of a literary work with a clinical case presentation; my review critiqued the book, not Mr. Styron's illness. A review of the latter based on an autobiographical work would be presumptive.

The link between alcohol dependence and depression is well documented, complex, and important. However, the thrust of *Darkness Visible: A Memoir of Madness* is Mr. Styron's illustrative and poignant portrayal of depressive illness.

Charleston, S.C.

Serotonin Function in Depression: Effects of Seasonality?

SIR: Lawrence H. Price, M.D., and colleagues (1) are to be commended for their study of responses to intravenous L-tryptophan (L-Trp) in such a large group of patients (N=126) and comparison subjects (N=58), but several questions are raised by their work. Contrary to previous reports in depressed patients, they reported that the mean peak Δ prolactin response following intravenous L-Trp was significantly *elevated* in melancholic patients (N=68, mean=4.2 ng/ml, SD=2.0) compared to control subjects (mean=3.1 ng/ml, SD=2.0, $p<0.03$). This surprising finding prompted me to review the published reports of prolactin responses to intravenous L-Trp in healthy control subjects (2-6), including all those referenced by the Yale investigators. In the ten studies which used doses of approximately 100 mg/kg (N=134) or 7 g (N=50), the mean peak Δ prolactin for healthy control subjects (of both sexes) ranged from 4.6 to 25.5 ng/ml with a mean of 13.8 ng/ml. This is substantially higher than the mean 3.1 (SD=2.0 ng/ml) reported by Dr. Price and colleagues.

In attempting to account for the variance in the system, the authors appropriately addressed the factors of age, gender, and nutritional status but did not account for a possible seasonal influence. In a study of 16 control subjects and 15 non-depressed bulimic patients, peak Δ prolactin responses following L-Trp, 100 mg/kg i.v., varied significantly by season (6). These data are compatible with other data in humans suggesting a nearly annual rhythm in normal 5-HT function (6). The reported variance attributable to seasonality in these studies is at least as great, if not greater, than that of gender and age. Interassay differences tend to be much lower and are probably not responsible for such variance. It would be a major contribution to the field of psychoneuroendocrinology if Dr. Price and colleagues reanalyzed their data assessing for a seasonal effect, e.g., by using a two-way analysis of variance using season and affective diagnosis as grouping variables in the total group and in each gender.

This brings up a statistical point. The authors decided to \log_{10} -transform their data "because of nonnormal distributions," although a review of mean peak Δ prolactin responses in table 2 of their article indicates little or no difference in the standard deviations for the various diagnostic groups. The parametric requirement for homogeneity of variance appears to have been met and, if so, \log_{10} -transformation is therefore unnecessary. In addition, only two of the other 14 published reports of prolactin responses following L-Trp have been \log_{10} -transformed.

TIMOTHY D. BREWERTON, M.D.
Charleston, S.C.

Dr. Price and Associates Reply

SIR: We thank Dr. Brewerton for his careful reading of our paper. We, too, were surprised by the enhanced prolactin response to intravenous L-Trp in melancholic depressed patients compared to control subjects. As we indicated, this may have reflected artifact (since it was entirely accounted for by differences in baseline plasma tryptophan) or differences in our sample of depressed patients compared to those studied by other investigators.

We were also aware of the lower mean peak Δ prolactin responses for healthy controls in our study relative to those reported by others. However, our baseline prolactin levels in all diagnostic groups were low as well, so that our peak Δ prolactin responses to L-Trp were proportionately similar to those reported in other studies. We carefully reviewed our assay methodology and found no evident reason for our low prolactin levels. We can only surmise that assay differences account for the discrepancy between our average levels and those of other investigators. In any case, all prolactin assays in our study were run using the same kit, so that observed differences between diagnostic groups should still be valid.

Although it is true, as Dr. Brewerton points out, that there was little difference in the standard deviations of the mean peak Δ prolactin responses across diagnostic groups, this does not alter the fact that the neuroendocrine responses were not normally distributed. In previous studies, we and others have surmounted this difficulty by utilizing nonparametric statistics. In the present study, we decided to use more powerful parametric methods in order to examine the effects of a large number of potentially confounding variables. Although our samples were sufficiently large to have perhaps justified the use of parametric statistics on the raw data, we decided to proceed more conservatively by applying the \log_{10} -transformation. Analysis of the untransformed raw data did not alter the major conclusions of the study.

Since submitting this paper, we have become aware of Dr. Brewerton's work on the seasonal variation of neuroendocrine responses to L-Trp. Preliminary analysis of our data appears to confirm a seasonal effect, again without any apparent effect on the major findings of our study. We are continuing our analyses and plan to publish the results when completed.

New Name for ECT Could Backfire

SIR: I understand the helpful intent of the authors who have argued for a new name for ECT, but I am concerned that such an effort could backfire (1, 2). It would take a long time, if ever, for the term "ECT" to be replaced by "cerebroversion" or another term. During that transition period, patients might be given information about and consent to "cerebroversion" only

to find out later from a friend, nurse, or other patient that what they in fact had received was "shock treatment." This belated discovery might undermine the patient's confidence and lead the patient to feel "tricked." It is for this reason I usually introduce the term "shock treatment" when discussing ECT with patients. A name change should take into account the additional confusion and suspicion it would generate.

REFERENCES

1. Kellner CH, Ramsey D: Please, no more "ECT" (letter). *Am J Psychiatry* 1990; 147:1092-1093
2. Morse JH, Short DD, Workman EA, Elnaggar KL: "Cerebroversion" instead of "ECT" (letter). *Am J Psychiatry* 1991; 148:1764

W. VAUGHN MCCALL, M.D.
Salem, N.C.

Dr. Kellner and Dr. Steele Reply

SIR: Change of any kind is difficult, as Dr. McCall suggests. Even after a less frightening term for ECT is adopted, old habits may persist. The difficult transition from *DSM-II* to *DSM-III* offers ample testimony to the staying power of terms and concepts that many believe have outlived their usefulness.

We think that finding a better name for ECT need be neither deceptive nor defensive. A part of obtaining informed consent, as outlined by one of our previous correspondents (1), can include mention of "shock therapy" as an earlier, albeit outdated, descriptor. We simply suggest that clinging to the phrases "shock" (or "electro" or "convulsive") as hallmarks of a treatment modality brings conceptual baggage that is both outdated and unnecessary. Similarly, we do not believe it is defensive to try to avoid frightening people gratuitously. Ideally, a new term will occupy the middle ground between the excessively graphic and the euphemistic.

Has the profession lost a precious heritage by replacing such terms as Mongolian idiot, moron, mental defective, or constitutional psychopathic inferior? Should psychiatric hospitals still be called insane asylums? Should we call stereotactic radiosurgery "X-ray brain cell incineration"? As we previously mentioned, the imaging technique known as nuclear magnetic resonance was renamed magnetic resonance imaging to avoid the frightening connotations of nuclear energy. This was neither deceptive nor defensive, but rather an effort to avoid needless anxiety. Because the change occurred early in the life of the technology, it aroused little opposition.

Little did we realize, when one of us (C.H.K.) proposed changing the name of ECT, that we were beginning a correspondence that would stretch over the next 2 years. Madison Avenue ignored our subsequent plea to help the field come up with a suitable name, and we are beginning to fear that this effort may be closer to the spirit of Pandora than Diogenes. Nevertheless, we maintain that clinging to the starkest possible words to describe the procedure is in no one's best interest—certainly not that of our patients, who may unrealistically fear one of the safest and most effective treatments in all of medicine.

Borderline Personality Disorder in Incest Victims

SIR: In the recent article by Elizabeth F. Pribor, M.D., and Stephen H. Dinwiddie, M.D. (1), the authors discussed lifetime prevalence of psychiatric illness in incest victims and comparison subjects. I was very surprised to see that borderline personality disorder was not listed among the diagnoses considered. Borderline personality disorder is well known to be associated with childhood sexual abuse, and it would have been interesting to compare the prevalence of this with other disorders. I wonder if Dr. Pribor and Dr. Dinwiddie would care to comment.

REFERENCE

1. Pribor EF, Dinwiddie SH: Psychiatric correlates of incest in childhood. *Am J Psychiatry* 1992; 149:52-56

JAMES KARAGIANIS, M.D., F.R.C.P.(C)
St. John's, Nfld., Canada

Dr. Pribor and Dr. Dinwiddie Reply

SIR: We agree with Dr. Karagianis regarding the importance of evaluating borderline personality disorder in adults with a history of childhood sexual abuse. Stone (1), Shearer et al. (2), and Ogata et al. (3), have recently reported on the prevalence of incest in hospitalized inpatients with borderline personality disorder. Brown and Anderson (4) reported an association of borderline personality disorder in those individuals with a history of childhood sexual and/or physical abuse in a large psychiatric inpatient sample. An assessment of the prevalence of borderline personality disorder in outpatient incest survivors would represent an important clinical contribution.

Our study design entailed interviews which were quite lengthy (3 hours on average). While we considered including other evaluations in the interview, including a standardized assessment of borderline personality disorder, time was a prohibitive factor. In addition to antisocial personality disorder on axis II and the axis I diagnoses reported in our article, we collected information about personality characteristics. We are presently examining this data for possible publication.

St. Louis, Mo.

The Treatment of Catatonia: Benzodiazepines or ECT?

SIR: We wish to respond to recent letters in the *Journal* concerning the treatment of catatonia (1-3). In particular we would like to address the contention of Stephen J. Masiar, M.D. (1), and Max Fink, M.D. (2), that ECT ought to be the first line of treatment for patients with this condition. Dr. Masiar refers to the "unique role ECT plays in reversing catatonia" while describing the "psychopharmacologic options" as "quite limited." Dr. Fink goes further, suggesting that physicians confronted with a catatonic patient should be "encouraged . . . to introduce ECT at the earliest opportunity." He supports this recommendation with the assertion that "catatonia is remarkably responsive to ECT" while the efficacy of benzodiazepines in treating this condition is "poorly founded in the literature."

We would suggest that the case for ECT as the treatment of first choice of catatonia is far less convincing than Dr. Masiar and Dr. Fink would have us believe. We are unaware of any published evidence that ECT is superior to sham ECT in treating catatonia and can find no randomized controlled studies demonstrating the superiority of ECT over pharmacotherapy with barbiturates or benzodiazepines. On the contrary, as Jeffrey D. DeLisle, M.D. (3), adroitly notes in his reply to Drs. Masiar and Fink, there is evidence that the barbiturate sodium thiopental, routinely used as anesthesia for patients undergoing ECT, may be just as effective as the convulsive treatments themselves in treating the catatonia.

In comparison with the data involving ECT, the evidence supporting the use of benzodiazepines to treat catatonia is relatively strong. In addition to over 35 case reports that have appeared since 1986, there are two larger series describing the rapid and robust response of catatonia to the benzodiazepine lorazepam (4, 5). In our own continuing study we have used low-dose lorazepam to treat 39 episodes of catatonia in patients admitted to our acute care psychiatric hospital ward. The mean age of these patients was 44.2 years, and the duration of the catatonia prior to treatment ranged from 2 days to 2 weeks. Following administration of 1-2 mg of lorazepam, 33 of the 39 episodes (82%) resolved completely within 3 hours. In two other instances the response was more delayed. High doses of lorazepam have not been required.

As mentioned in our earlier article, there appears to be a tendency for catatonic patients to relapse unless the lorazepam is maintained during the initial treatment of the underlying illness. To date none of the patients studied has gone on to require ECT for their catatonic state.

The advantages of lorazepam over ECT in the treatment of catatonia are as follows:

1. The response to lorazepam is apparent within a matter of hours.
2. Low-dose lorazepam is an extremely safe intervention with minimal side effects.
3. Catatonic patients, by virtue of their mutism, immobility, and withdrawal, are generally unable to give informed consent. Treatment then requires consent from next of kin. In our experience families are far more willing to give consent for medication than for ECT.
4. If a patient responds to an initial dose of lorazepam and becomes cooperative and verbal, it is then possible to do a full interview to determine the underlying psychiatric diagnosis and to assess whether he or she is competent to make decisions regarding further treatment.

We fully recognize that, once the catatonic syndrome has resolved and a full assessment can be made, ECT may prove to be the treatment of choice for the underlying illness for

some patients. What we are disputing is the recommendation that ECT be used as a first-line treatment for the catatonia itself.

We hope these comments might serve to give a more balanced appreciation of the treatment options available for this condition.

Dr. Masiar Replies

SIR: I appreciate the concern of Dr. Rosebush and associates regarding treatment strategies of catatonia wherein they caution against ECT as a first-line treatment for this disorder. In my initial response to the report by Dr. DeLisle I described a definitive treatment approach for catatonic states which may evolve from a variety of syndromes. Abrams and Taylor (1, 2) have carefully delineated the predominant underlying etiology of catatonia as usually major affective disorder, most often the manic phase of bipolar illness. Clinicians are well aware of the extreme danger manic delirium may represent. As such, I continue to advise early consideration of ECT for these patients, as the usual practice of exhausting all pharmacologic options prior to recommending a clearly safe and effective modality seems unsupportable.

Dr. Fink Replies

SIR: Dr. Rosebush and colleagues are fortunate in their success with lorazepam in relieving symptoms of catatonia. In arguing against the use of ECT as a first-line treatment for catatonia, I believe they are setting up a straw man.

They argue that our suggestion that ECT be considered in the treatment of catatonia, regardless of associated symptomatology or diagnosis, is too encouraging and that the efficacy of ECT in such conditions is unproven. They describe

their success: "Following administration of 1–2 mg of lorazepam, 33 of 39 episodes (82%) resolved completely within 3 hours. In two other instances the response was more delayed." They account for 35 patients. I would enquire as to the fate of the four patients who seemingly failed to respond; did they recover spontaneously or go on to an unfavorable outcome?

I raised the question of ECT in the context of a report by DeLisle (1) of a schizophrenic patient with severe catatonia who temporarily responded to midazolam, but when repeated administrations failed "she began refusing all medication, suffered a partial catatonic relapse and worsening of psychosis, and went on to a prolonged course of illness." We suggested that ECT should have been considered, providing support for this view from the historic literature.

We recently reviewed the hospital records of patients identified as schizophrenic, catatonic type, on their admission or discharge diagnoses between 1985 and 1990 (unpublished, in preparation). We identified 20 patients who had received a wide range of treatments. Ten had received repeated courses of benzodiazepines, mainly lorazepam, without success. Nine of these received ECT; eight responded well and were discharged much improved or recovered. Four were discharged with diagnoses of major depressive disorder, with psychosis and catatonia, and four with diverse organic affective disorders. It was this salutary experience, in the face of failures with benzodiazepines, that led to my comment on the case reported by DeLisle. The course of one of the patients was reported by Fricchione et al. (2).

Fricchione (3) recently reviewed the experience with benzodiazepines in catatonia. He noted many reports of success but cites instances in which these drugs failed. He concluded: "Given the significant morbidity and mortality associated with catatonia, ECT should be considered if an expeditious 48- to 72-hour benzodiazepine trial is unsuccessful." That is our present practice.

It is useful to realize that the syndrome of catatonia is no longer "scarce." It is gratifying that the *DSM-IV Options Book* (4) proposes to recognize catatonia as a modifier of various axis I diagnoses, including affective disorders and organic affective disorders. Such recognition will surely encourage the use of ECT in catatonic patients when a trial of benzodiazepines fails, for it will free practitioners from the limitations inherent in the teaching that ECT is not indicated in patients with schizophrenia.

Childhood Factors in Adult Self-Destructive Behavior

SIR: The otherwise excellent article by Bessel A. van der Kolk, M.D., and colleagues (1) on childhood factors in adult

self-destructive behavior contains two misleading statements that are not really supported by their data.

They state, "The earlier the trauma, the more cutting." However, what they found was that trauma from adolescence was related to suicide attempts alone, whereas trauma from early childhood and latency was also related to cutting. Moreover, the findings from early childhood and latency were the same. The analysis should have used age of trauma as a continuous variable to clarify whether it was related to the severity of any particular symptom.

They also state, "Although childhood trauma contributes heavily to the initiation of self-destructive behavior, lack of secure attachments maintains it." However, what the authors found was that neglect correlated with self-destruction at intake and was a more stable predictor of the continuation of self-destructive behavior during the study, which does not necessarily shed light on the origins of such behavior during childhood development. Another plausible explanation is that, since all these patients were in treatment, when these behaviors were related to trauma the patients were more approachable in therapy, while when the behaviors were related to neglect, treatment was less effective.

JOEL PARIS, M.D.
HALLIE FRANK, PH.D.
Montreal, Que., Canada

Dr. van der Kolk and Associates Reply

SIR: We are somewhat surprised by the complaint in the letter by Dr. Paris and Dr. Frank that the data in our article do not substantiate our statement, "The earlier the trauma, the more cutting." This clearly represents an incorrect reading of our data. As they suggested, we did use age of trauma as a continuous variable to see whether it was related to the severity of any particular symptom. In table 3 of our article we showed that trauma in infancy was related to cutting at the $p < 0.001$ level; trauma during latency at the $p < 0.01$ level. In contrast, there was only a trend in the relationship between trauma in adolescence and cutting. Thus, the relationship between trauma and cutting clearly diminished with age.

Similarly, our data clearly supported our statement that trauma contributes heavily (though not exclusively) to the initiation of self-destructive behavior, while lack of secure attachments maintains it. Trauma was the most important predictor of self-destructive behavior prior to our subjects' entrance into our study. However, after being in the study for an average of 4 years, and usually receiving considerable psychotherapy, it was the subjects with the most severe histories of neglect (and sexual abuse) who continued to engage in self-destructive behavior (see table 4). As we stated in our discussion, the subjects with histories of severe childhood neglect seemed to be at least capable of making use of interpersonal relationships during adulthood to help them stop their self-destructive behavior. We thus agree with the critique's "alternative" explanation that "when these behaviors were related to

trauma the patients were more approachable in therapy, while when the behaviors were related to neglect, treatment was less effective," and stated so in our article.

Antidepressants and the Treatment of Stuttering

SIR: John Paul Brady, M.D. (1), recently reviewed the pharmacology of stuttering. I found this review timely and wide in scope. However, by stating that antidepressants have not been evaluated in the treatment of stuttering, Dr. Brady prompted me to inform you that I (2) treated 19 stutterers with mianserine, 30–60 mg/day, for 3 weeks. Twelve of them had Hamilton and Zung scores in the depressed range. Predominantly clonic stuttering was more frequent among these twelve patients ($p=0.03$, Fisher's exact test) than in the remaining stutterers.

Ten of the stutterers with depressive scores and one without a depressive score responded well to mianserine in terms of their stuttering ($p=0.01$, Fisher's exact test). All stutterers with predominantly clonic dysfluency responded to mianserine. Improvement in Hamilton and Zung scores was significantly correlated with the changes in the number of dysfluencies, except for loud reading. Six stutterers who responded to mianserine reported drowsiness in the first 5 days of treatment.

I agree with Dr. Brady that fluoxetine and clomipramine deserve evaluation in stuttering.

Toronto, Ont., Canada

Dr. Brady Replies

SIR: Dr. Costa's interesting abstract eluded my computer-aided search of the literature. It is one of few efforts to identify a subclass of stutterers who may be selectively responsive to a particular medication. In this study, patients with "clonic" stuttering (i.e., those with a preponderance of repetitions of speech sounds rather than prolonged blocks in the flow of speech) benefited the most from mianserine. This drug is a tetracyclic which strongly inhibits the reuptake of serotonin. It is not available in the United States. Controlled clinical trials of mianserine and other antidepressants with strong serotonin reuptake inhibiting properties (e.g., clomipramine, fluoxetine, fluvoxamine, sertraline) would be interesting. I understand that trials of some of these agents in the treatment of stuttering are in progress.

Alexithymia and the ECA Study

SIR: Gregory E. Simon, M.D., M.P.H., and Michael Von Korff, Sc.D., (1) have reported interesting data from the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) first-wave results regarding the relationship of somatization to psychological or emotional distress and diagnosis. They find that patients with multiple somatic symptoms also report multiple emotional symptoms and frequently meet criteria for psychiatric diagnoses. They go on to conclude that, because subjects with high levels of somatic symptoms also have high levels of psychiatric distress, alexithymia, a construct used to describe people who have difficulty recognizing or discussing emotional issues, should not be extended to somatizing patients. I question this assertion.

The original descriptions of alexithymia were rooted in clinical material from patients who demonstrated difficulty discussing their emotional states, had a paucity of fantasy life, and had a concrete, reality-based pattern of communication (2–5). As originally described, often these patients could identify a feeling or affective state but had difficulty amplifying upon this verbally. For example, a patient might be able to say "I am angry," but be unable to elaborate how he or she was aware of this anger or what thoughts or fantasies preceded or accompanied this feeling. The structure of the NIMH Diagnostic Interview Schedule (DIS), the instrument used to assess symptoms, does not require respondents to identify, discuss, or expand upon any particular symptom. Rather, they merely have to endorse it in a yes or no format.

Alexithymic patients may very well be able to do this, yet be unaware of the depth or significance of the feeling which they have endorsed. The measuring of alexithymia has been problematic, and I suggest caution in "rating" alexithymia based upon the number of items positively endorsed from a checklist. Furthermore, prevailing views have blurred the distinction between "psychosomatic disorders" and other disorders that have both somatic and psychic components, making the distinction between psychosomatic disorders and somatizing patients less clear.

Another concern with the interpretation of the data stems from the well-known tendency toward co-occurrence which has been shown in the NIMH ECA data (6). It may be that subjects who endorsed symptoms of psychiatric distress also endorsed symptoms of somatic distress, thus making it likely that if they had a psychiatric disorder, they would likely show many somatic symptoms as well. Again, concluding "that masked psychiatric morbidity among the high somatization group was atypical" fails to take this into account and discounts the meaning and attribution of symptoms which is quite germane to the concept of masked symptoms.

I believe that the authors importantly point out the high co-occurrence between psychiatric and somatic symptoms. However, alternate explanations for this need to be considered before firm conclusions can be drawn.

IRA M. LESSER, M.D.
Torrance, Calif.

Dr. Simon and Dr. VonKorff Reply

SIR: We agree with Dr. Lesser that an epidemiologic assessment such as the DIS cannot provide the same understanding as a clinical assessment. Consequently, our results do not argue against the existence or importance of alexithymia in any individual patient. In the community sample we described, however, functional somatic symptoms did not typically function as defenses against awareness of psychological distress. "Somatizers" were aware of and quite willing to report anxiety and depression.

We also agree that the distinction between psychosomatic disorders and somatization remains unclear, but we hope that our findings might sharpen it. Descriptions of alexithymic patients with classic psychosomatic diseases (hypertension, peptic ulcer) emphasize the physical consequences of denying or avoiding psychologic distress. Somatizing patients, however, usually display an increased sensitivity to all types of distress, both physical and psychological. The two groups might be regarded as lying on opposite ends of a spectrum of symptom sensitivity.

Many multisymptom patients freely acknowledge that their physical symptoms and emotional distress are intertwined. Medical and mental health providers, however, may focus on or give credence to only one domain. Effective, patient-centered care will require providers and patients to integrate the physical (e.g., pain or fatigue), emotional (e.g., depressed mood or anxiety), and behavioral (e.g., reduced activity or social withdrawal) components of illness.

Antidepressant-Induced Mania in Obsessive-Compulsive Disorder

SIR: Warren Steiner, M.D., C.M. (1), has recently reported a case of fluoxetine-induced mania in a patient with obsessive-compulsive disorder. The author's patient presented a good response to 20 mg/day of fluoxetine with regard to her obsessive-compulsive disorder but soon developed a hypomanic syndrome and her dose of fluoxetine had to be lowered. This led to the recurrence of obsessions and compulsions, but a subsequent increase to the initial fluoxetine dose plus addition of clonazepam, 0.5 mg/day, finally succeeded in keeping the patient asymptomatic of both mood and obsessive features. The author concludes that all patients treated with fluoxetine, regardless of primary psychiatric diagnosis, should be monitored for the development of mania.

A more significant finding, nevertheless, involves the fact that Dr. Steiner's patient finally remained euthymic and free of obsessive-compulsive symptoms. Antidepressant-induced

mania in obsessive-compulsive patients has already been reported elsewhere (2, 3), but both reports stated the impossibility of keeping the patient euthymic without the recurrence of obsessive-compulsive disorder. We recently reported a case of recurrent clomipramine-induced mania in a patient with obsessive-compulsive disorder (4). Neither lowering clomipramine dose nor adding lithium carbonate or neuroleptics succeeded in keeping the patient asymptomatic of both mood and obsessive features. Interestingly, obsessive-compulsive symptoms remitted during the manic episode but reemerged insidiously as soon as the manic syndrome responded to treatment and/or clomipramine was lowered. During the past 3 months this patient was treated with fluoxetine, but while she did not become manic again, her severe obsessions and compulsions unfortunately were refractory to even high doses of this drug.

An inverse relationship has been postulated between obsessive-compulsive disorder and mania (3). Indeed, primary mania is an extremely rare complication of obsessive-compulsive disorder. We have suggested that abnormal regulation of brain serotonergic function might be related to at least some aspects of this supposed pathophysiological relationship (4). Since fluoxetine, a selective serotonergic antidepressant, clearly induced mania as long as obsessive symptoms improved in Dr. Steiner's patient, we might consider this hypothesis further supported. However, since that patient finally reached euthymia free of obsessive-compulsive symptoms, one might speculate that some other mechanisms and neurotransmitters should be involved. Despite its high potency inhibiting serotonin reuptake, clomipramine also has noradrenergic properties, which should be considered with regard to the previous case reports on this issue. Such cases as Dr. Steiner's illustrate that the role of antidepressants inducing mania in several types of psychiatric patients deserves further research.

EDUARD VIETA, M.D.
MIQUEL BERNARDO, M.D., PH.D.
Barcelona, Spain

Dr. Steiner Replies

SIR: Dr. Vieta and Dr. Bernardo raise the interesting question of the relationship between mania and obsessive-compulsive disorder and of the pharmacological basis of the manic switchover in these patients. It is likely that the switchover processes in obsessive-compulsive disorder patients and in patients with mood disorders are different, as various antidepressants seem to present a different risk of development of mania when used in patients with obsessive-compulsive disorder or mood disorder. In obsessive-compulsive disorder pa-

tients treated with fluvoxamine, Jefferson et al. (1) found a 25% switchover, while in mood disorder patients treated with fluvoxamine a 0.6% incidence has been reported (2), indicating that patients that with obsessive-compulsive disorder may be at greater risk of developing mania. However, with other serotonin-specific reuptake blockers this dramatically increased rise for obsessive-compulsive disorder patients has not been found. Sertraline, which has been found to be ineffective in treatment of obsessive-compulsive disorder (3), has not as yet been reported to precipitate manic episodes in patients with obsessive-compulsive disorder. This lower risk of a manic switch with a medication that is ineffective in treating obsessive-compulsive disorder may in fact support the hypothesis of an inverse relationship between obsessive-compulsive disorder and mania. This relationship could also be explained by the greater selectivity for serotonin reuptake blockade compared to noradrenaline reuptake blockade found with sertraline when compared to other serotonin specific reuptake blockers (4). It is possible that a certain minimum blockade of noradrenaline reuptake is essential for treatment of obsessive-compulsive disorder as well as for the development of mania in these patients. An interesting report of the use of metergoline in reversing clomipramine-induced improvement in obsessive-compulsive disorder symptoms (5) leads one to wonder whether serotonin antagonists could also reverse antidepressant-induced mania in obsessive-compulsive disorder patients who switchover. If so, this would certainly support the hypothesis of an inverse relationship between mania and obsessive-compulsive disorder.

WARREN STEINER, M.D.
Montreal, Que., Canada

Obsessive-Compulsive Disorder in Relation to Body Dysmorphic Disorder

SIR: We read with interest the recent article on body dysmorphic disorder by Katherine A. Phillips, M.D. (1). Dr. Phillips suggested that body dysmorphic disorder is related to obsessive-compulsive disorder, and that dynamic factors are also involved. We recently evaluated a patient who appeared to meet criteria for both obsessive-compulsive disorder and body dysmorphic disorder.

Ms. A was a 17 year old who presented complaining of compulsive skin picking and feared disfigurement. The pa-

tient had been experiencing intrusive and distressing images of "pus" under her skin pores for 4 years. She began to pick her skin at a mirror, using a pin to get the "pus" out. She had no concern over her skin's natural appearance, realizing no one else could see the alleged problem. Nonetheless, she was unable to pass a mirror without picking her face, shoulders, back, and breasts, ultimately causing some skin changes. She would spend a half hour in the shower to undo the damage. She was unable to stop her behavior.

Six months of dynamic psychotherapy failed to relieve her symptoms. Ms. A achieved considerable insight into her symptoms. The patient's mother, a university anthropologist, had impressed upon the patient the diversity of beauty in various cultures. However, clear skin, her mother stressed, was valued throughout the world. Following this discussion, the patient experienced the intrusive images. In therapy, the patient learned how conflicted and ambivalent her relationship was with a perfectionist and controlling mother who focused on skin. Also a perfectionist, the patient became even more distressed with imagined damage she was doing to her skin.

Mental status evaluation revealed a young woman with very mild acne. She showed obvious embarrassment at her symptoms but was not able to control her compulsive skin picking. Her Yale-Brown Obsessive Compulsive Scale score was 24; Beck Depression Inventory score was 9. The patient and her parents requested behavioral therapy.

Jenike (2) suggested that compulsive face picking is a relatively rare disorder seen primarily in young women with mild acne, responding to treatments useful in obsessive-compulsive disorder. Our patient did not limit the picking to just her face but appeared otherwise similar to Jenike's patients. Our patient met full criteria for both obsessive-compulsive disorder and body dysmorphic disorder. Other reports stress that body dysmorphic disorder may respond to serotonergic antidepressants useful in obsessive-compulsive disorder (3). As Thomas (4) suggested, body dysmorphic disorder may be primary or secondary, and in our patient it appeared to be secondary to a primary obsessive-compulsive disorder. It is possible that character traits, obsessiveness and perfectionism, would predispose this patient to both disorders.

From a dynamic perspective, Ms. A's mother was dominant, perfectionist, and focused on skin. The patient attempted unsuccessfully to neutralize anxiety around her conflict with her mother through repression and displacement. Intrusive images were the symptom of this conflict, not imagined ugliness. Anxiety was defended against through classic doing and undoing. The behavior resulted in minor skin changes, about which the patient became phobic and avoidant.

We thank Dr. Phillips for her cogent discussion of the complex interrelationship between body dysmorphic disorder and obsessive-compulsive disorder. We hope our case has been helpful and illustrative.

JOHN TANQUARY, M.D.
MINDA LYNCH, PH.D.
PRAKASH MASAND, M.D.
Syracuse, N.Y.

Dr. Phillips and Dr. McElroy Reply

SIR: We read the letter by Dr. Tanquary and associates with great interest, as it raises important questions about the interface between obsessive-compulsive disorder and body dysmorphic disorder (a preoccupation with an imagined defect in appearance). Published cases of compulsive face picking (1) have conceptualized this behavior as a form of obsessive-compulsive disorder. To our knowledge, Dr. Tanquary and colleagues are the first to note a relationship between compulsive face picking and body dysmorphic disorder.

We, too, have noted a relationship between compulsive face picking and body dysmorphic disorder. In our ongoing study of body dysmorphic disorder, we have encountered nine patients (four women and five men) with repetitive, time-consuming face picking. Eight of nine patients considered this behavior to result from their body dysmorphic disorder, which in seven cases consisted of typical preoccupations with imagined or minimal acne. The eighth case was less typical; like Dr. Tanquary's patient, the patient picked to remove imagined pus from beneath her skin to prevent it from surfacing on her skin and making her ugly. In some cases, the picking caused actual mild facial scarring, which intensified the body dysmorphic disorder symptoms. The ninth patient, unlike the others, considered her face picking to be primary; i.e., not a reaction to her body dysmorphic disorder. Instead, the mild resulting disfigurement caused body dysmorphic disorder symptoms.

Is repetitive face picking best conceptualized as body dysmorphic disorder or as obsessive-compulsive disorder? Is it sometimes the former and sometimes the latter? Unlike Dr. Tanquary and his colleagues, we consider the face picking of eight of our nine patients to be a symptom of their body dysmorphic disorder. This behavior was a response to a preoccupation with an imagined or greatly exaggerated "defect" in their appearance. Thus, repetitive face picking appears to be one of the many ritualistic behaviors that can occur in body dysmorphic disorder, which include repetitive mirror checking, persistent questioning or requests for reassurance, and repetitive grooming behaviors, such as hair combing or makeup application. Although certain repetitive—and sometimes self-mutilatory—grooming behaviors have been conceptualized as a form of obsessive-compulsive disorder (trichotillomania, compulsive hand washing, and onychophagia [nail biting] in humans [2]; compulsive paw licking in dogs [canine acral lick]; and feather picking disorder in birds [3]), some compulsive grooming behaviors (e.g., hair arranging and face picking) should, in some instances, be considered a complication of body dysmorphic disorder.

But what about the relationship between obsessive-compulsive disorder and body dysmorphic disorder themselves? Might they be related or even the same disorder? The answer to this question is unknown, but it appears that these disorders may be related, given their similar early age of onset, often chronic course, apparent high comorbidity with mood and anxiety disorders, substantial functional impairment and similar phenomenology—both consisting of persistent, intrusive

thoughts that are difficult to resist as well as compulsive, ritualistic behaviors (4). In addition, preliminary evidence suggests that body dysmorphic disorder may, like obsessive-compulsive disorder, respond to treatment with serotonergic antidepressants (5, 6). On the other hand, there appear to be differences between these two disorders. In our experience, patients with body dysmorphic disorder are less likely than those with obsessive-compulsive disorder to have insight into the senselessness of their preoccupations; that is, their preoccupations are more likely to consist of overvalued ideas or delusional thinking. It also appears that the ritualistic behaviors of body dysmorphic disorder, such as repetitive mirror checking, are less likely to temporarily relieve anxiety. Body dysmorphic disorder also appears to often cause more social impairment and isolation. Research is needed to confirm these impressions and to further explore the interface between these two disorders.

Most of our patients were extremely reluctant to discuss either their body dysmorphic preoccupations or their compulsive face picking and did so only when asked about them. Thus, it is important that clinicians specifically inquire about the presence of compulsive face picking in body dysmorphic patients and about body dysmorphic disorder in compulsive face pickers. Body dysmorphic disorder often has serious consequences, including social isolation, unemployment, hospitalization, and suicide—associated features that go beyond simple face picking and are important for clinicians to be aware of.

Simple Schizophrenia, Negative Symptoms, and Prefrontal Hypodopaminergia

SIR: Kenneth L. Davis, M.D., and associates (1) have reviewed evidence suggesting that schizophrenia is characterized by subcortical hyperdopaminergia and prefrontal hypodopaminergia. It is likely that this conception of the role of dopamine in schizophrenia will generate a great deal of research and stimulate new treatment approaches.

An especially provocative component of this hypothesis is that prefrontal hypodopaminergia is associated with the development of negative symptoms. There are two approaches to research on the treatment of schizophrenia that have provided

data consistent with this hypothesis and that have the potential to refine our understanding of hypodopaminergia in schizophrenia. One of these involves the use of dopamine precursors and agonists in the treatment of schizophrenia spectrum disorders such as schizoid or schizotypal personality, in which negative symptoms can be especially prominent (1). As yet, neither schizoid nor schizotypal personality disorder has been studied in this way. However, a beneficial effect of L-dopa has been reported in a double-blind crossover trial examining patients with simple schizophrenia (2). Simple schizophrenia is a subtype of schizophrenia defined by the absence of delusions and hallucinations and a corresponding predominance of negative symptoms. The results of this study are therefore consistent with the hypothesis that hypodopaminergia underlies negative symptoms. Although this study does not appear to have stimulated additional trials of dopaminergic agents in simple schizophrenia, diagnostic criteria for this subtype that could facilitate such research have been proposed (3, 4).

A second approach to investigating prefrontal hypodopaminergia examines dimensions of positive and negative symptoms rather than subtypes. In such research, patients are assessed on both of these symptom dimensions and their response to trials of dopamine precursors or agonists are evaluated. Based on the hypothesis that hypodopaminergia underlies negative symptoms, it can be predicted that negative symptoms will demonstrate a greater beneficial response to dopamine agonists than positive symptoms. Such an effect has been reported in trials of L-dopa (5) and amphetamine (6) in patients with schizophrenia.

Research on the effects of dopamine agonists in schizophrenia would be more informative if selective mesocortical dopamine receptor agonists were studied, for example, selective D₁ agonists (1). In such studies, it will also be important to examine separately negative symptoms and interpersonal deficits, a distinction with important theoretical and empirical implications that has often been neglected in research on negative symptoms.

ROBERT H. DWORKIN, PH.D.
LEWIS A. OPLER, M.D., PH.D.
New York, N.Y.

Dr. Davis and Associates Reply

SIR: Dr. Dworkin and Dr. Opler call particular attention to the possibility that prefrontal hypodopaminergia is associated

with the development of negative symptoms, and that these can be treated with L-dopa. We heartily agree that patients within the schizophrenia spectrum who are relatively devoid of positive symptoms might benefit from trials that enhance dopaminergic activity. Obviously a major question that ultimately must be addressed is the most effective agent to use for selective augmentation of dopaminergic activity in cortical regions. Although L-dopa remains an interesting possibility, it surely will be increasing noradrenergic activity as well. This may, or may not, be beneficial. Dopamine agonists offer another approach, but the ideal dopamine receptor to activate, as well as how to maximize regional selectivity, remains a pharmacological dilemma.

One interesting approach to this problem has been the administration of the dopamine reuptake blocker mazindol. As recently reported (1), mazindol in combination with neuroleptics in a naturalistic outpatient setting was able to substantially reduce negative symptoms. This is an interesting approach that deserves further attention, particularly if, in combination with neuroleptics, mazindol may have a unique effect on cortical dopaminergic neurons.

A critical element in our reconceptualization of the role of dopamine in schizophrenia is the bidirectionality of dopamine. Hypodopaminergia in the cortex may be associated with hyperdopaminergia in subcortical regions. Recently this possibility received some support from a study in which cerebral blood flow was measured by single photon emission computed tomography. Schizophrenics following the Wisconsin Card Sorting Test were found to have diminished frontal cortical blood flow and increased striatal blood flow compared to control subjects completing the same task (2). The mechanism that may lead to such bidirectionality has received considerable attention at the preclinical level (unpublished paper by A.Y. Deutsch). An excitatory glutamatergic tract whose activity is diminished following cortical hypofunction may serve to mediate subcortical hypodopaminergia. Thus, isolation of the glutamatergic receptor subtype that modulates this subcortical dopaminergic response is clearly of interest and may offer an approach to the treatment of schizophrenia.

Prevalence of Substance Abuse or Dependence Diagnoses on an Inpatient Inner City Psychiatric Unit

SIR: The 40% prevalence of substance abuse in psychiatric patients cited in a letter by Edward B. Gogek, M.D. (1), and in studies done by Crowley et al. (2) is relatively high; however, it is much lower than in the population I serve. Dr. Gogek's letter prompted me to review 50 consecutive discharges in the first half of 1991 from my acute inpatient general psychiatry service.

The center is a comprehensive state community mental health center with acute inpatient units in the inner city, serving a socially disadvantaged catchment area of over 160,000. The facility's policy is not to admit those with a primary diagnosis of substance abuse disorder or those with private health insurance or government medical assistance. I was not the admitting psychiatrist but I was the attending psychiatrist of all patients studied.

The prevalence of a substance abuse or dependence disorder on discharge (dually diagnosed) was 70%. Sixty-six percent of the patients were male; the median age was 33.2 years (only five patients were older than 45); 70% were Afro-American, 28% white, and 2% Native American. Almost all were currently unmarried. Seventy-six percent of the men had substance abuse diagnoses versus 59% of all women. Sixty-three percent of the Afro-Americans, 79% of the whites, and the one Native American had substance abuse diagnoses. The median age of the substance abusers was 32.7 years; median age of the nonsubstance abusers was 34.4 years. Excluding substance abuse diagnoses, principal diagnoses were schizophrenia, schizophreniform, or schizoaffective disorder in 30% (N=15) of the patients; organic mental disorder in nine patients; bipolar disorder in eight patients; psychosis, not otherwise specified in six patients; unipolar depression in three patients; substance dependence diagnosis in one patient; and other diagnoses in eight patients.

This study supports findings that "being younger, male, non-married, and of a lower socio-economic status" are associated with increased alcohol or other drug use (3). My population differs from that of Dr. Gogek's in that it is an inner city inpatient population. As patients with dual diagnoses are "less able to manage their lives in the community" than those with mental illness alone, one would expect a higher percentage of substance abuse diagnoses in those acutely hospitalized (4). Safer (5) found persistent substance abusers had a psychiatric hospitalization rate greater than 2.5 times higher than patients who had a past but not current history of substance abuse and patients with little or no substance abuse history. Also, I cite a figure over twice that of Crowley in his late 1971 sample of 50 consecutive admissions (2). Since that time there has been an increase in recognition and in absolute numbers of those with dual diagnoses (e.g., Crowley's study was before the crack cocaine epidemic).

Treatment studies generally exclude subjects with additional diagnoses, but this is not true in practice, where patients can present with a number of disorders. Regier (6) cites results from the ECA study that among those with a mental disorder, the odds ratio of having some addictive disorder was 2:7. In fact, 60.7% of patients with bipolar I disorder have a dual diagnosis; so it is the exception rather than the rule to find a person with bipolar I disorder without a substance abuse diagnosis (6).

Psychiatrists must be alert to substance abuse in their patients. Outside sources for historical material and perhaps toxicology screens "should be more systematically obtained," especially in hospitals where young adult chronic patients are evaluated (5). We must be cautious in diagnosing "functional" psychosis or other diagnoses when substance abuse is involved.

Importantly, the high prevalence rate of dual diagnoses brings sharply into focus the need for professionals, psychiatrists and others, to be well-trained in dealing with this population.

DANIEL D. STORCH, M.D.
Baltimore, Md.

Dr. Gogek Replies

SIR: Dr. Storch has brought up several important aspects of the interface between psychiatry and substance abuse treatment. First is a marked variability in the rates of substance abuse among psychiatric populations. Dr. Storch's rate of 70% is nearly twice the 40% reported in my letter. However he enumerated several demographic factors that contributed to this higher rate. His data support the contention that substance abuse occurs at higher rates in psychiatric populations than in the general population.

Second is that these high rates occur in psychiatric facilities with a policy not to treat patients with primary substance abuse diagnoses. While such a policy is often reasonable and necessary (e.g., for insurance purposes or to prevent psychiatric units from turning into detoxification units), it can lead to seemingly absurd situations, such as on Dr. Storch's unit, where, despite this policy, substance abuse is the most common diagnosis. It would be more accurate to state that the policy is not to admit patients whose only primary psychiatric diagnosis is substance abuse. Otherwise, it misleads clinicians by saying that they are not treating primary substance abuse disorders. Dr. Storch's data and my own show that this is not true. Both of our samples had high rates of primary substance abuse disorders.

Third, Dr. Storch says we need to be alert to substance abuse among our patients. I strongly concur. For this reason, surveys showing the prevalence of substance abuse among various psychiatric populations are very useful.

EDWARD B. GOGOK, M.D.
Prescott, Ariz.

Blunting Growth Hormone Release in Mania

SIR: We take issue with three statements made in the report by Timothy G. Dinan, M.D., and associates (1). First, they stated that growth hormone (GH) responses to clonidine and desmethylinipramine have not previously been studied in mania, but they have overlooked a number of findings. Ansseau et al. (2) found blunted responses to clonidine in groups of patients meeting Research Diagnostic Criteria for mania and major depression, compared with minor depression. Blunted GH responses to clonidine in mania were also found by Watanabe et al. (3).

Second, we disagree that blunted GH responses to noradrenergic stimulation are a "marker for affective disorder." The sensitivity of such testing is limited. The authors' own study with desmethylimipramine found blunting (<5 ng/ml increase) in only 48% of DSM-III-R-diagnosed patients with major depression (4). Specificity is questionable, given that blunted responses have been reported in generalized anxiety, panic and obsessive-compulsive disorders, Alzheimer's disease, alcoholism, and essential hypertension (5, 6).

Third, although the action of desmethylimipramine on GH is mediated by α_2 -adrenoceptors, it does not follow that blunting indicates their down-regulation. Several groups have shown decreased GH responses to growth hormone-releasing hormone (GH-RH) in depression and panic disorder, making interpretations of neurotransmitter sensitivities problematic.

Tests of noradrenergic receptor sensitivity that allow measures of presynaptic function (noradrenaline and 3-methoxy-4-hydroxyphenylglycol release, cardiovascular and sedation responses) may be more informative than the sole report of postsynaptic responses permitted by using the reuptake blocker desmethylimipramine. Simultaneous measurement of somatomedin C may throw some light on factors influencing pituitary responsiveness, but the difficulties of measuring somatostatin input and GH-RH remain a barrier to understanding the mechanisms in patients.

NICK COUPLAND, MB.CHB, M.R.PSYCH.
PAUL GLUE, M.R.C.PSYCH.
Bristol, Great Britain

Dr. Dinan and Associates Reply

SIR: Regarding the comments of Dr. Coupland and Dr. Glue, we accept that Ansseau et al. previously reported on clonidine/growth hormone responses in mania. We were unaware until recently of this publication.

In our inpatient population the sensitivity of the desipramine/growth hormone stimulation test is around 70% in the diagnosis of major depression. We have previously questioned the specificity of the test, reporting significant blunting in patients with irritable bowel syndrome (1) and alcoholism (unpublished). We do not accept that patients with obsessive-compulsive disorder show such blunting (2).

The release of growth hormone from the anterior pituitary is under complex control. Following the stimulation of noradrenergic receptors there is clearly a cascade of biochemical processes preceding the release of growth hormone. Blunted release in depression may be due to abnormalities at any point in the cascade. Down-regulation of noradrenergic α_2 -receptors is just one possible interpretation of the data.

Correction

The address for Lawrence A. Labbate, M.D., author of the letter "Nicotine Cessation, Mania, and Depression" (May 1992 issue, p. 708), is Bremerhaven, Germany.

Highlights of the 145th Annual Meeting

The 145th Annual Meeting of the American Psychiatric Association was held in Washington, DC, May 2-7, 1992. The total registration was 14,704, including 7,764 members; 1,616 spouses, other family members, and guests; 3,589 nonmembers; 1,261 exhibitors; 220 members of the media; and 254 staff members.

Business Meeting

The Annual Business Meeting was called to order by Lawrence Hartmann, M.D., in the Washington Convention Center on Sunday, May 3, at 12:30 p.m.

First Session. Richard M. Bridburg, M.D., Recorder, announced the presence of a quorum. Dr. Hartmann then asked the audience to observe a moment of silence in memory of all members and Fellows who died during the past year. John Zinner, M.D., chairperson of the Committee of Tellers, announced the results of the election of officers and trustees. The reports to the membership followed. Steven S. Sharfstein, M.D., presented the Secretary's report, which was followed by the reports of Mary Jane R. England, M.D., Treasurer; Thomas Pfaffler, M.D., Speaker of the Assembly; Ronald A. Shellow, M.D., Speaker-Elect of the Assembly; Henry E. Payson, M.D., chairperson of the Committee on the Constitution and By-Laws; and Aron S. Wolf, M.D., chairperson of the Membership Committee. Melvin Sabshin, M.D., presented the Medical Director's report. Reports of all the councils were also available. All reports were accepted by the membership as submitted and will be published in the October 1992 issue of the *American Journal of Psychiatry*. Dr. Hartmann then recessed the first session of the business meeting.

Second Session. Following the business meeting Dr. Hartmann called the Annual Forum, for all voting members, to order. Dr. Hartmann opened the Forum and recognized Dr. Nathaniel Lehrman, from the Nassau County District Branch. Dr. Lehrman addressed the body with his intention to appeal his Medicaid fraud conviction. He also notified the body of his leadership in a psychiatric survivors group workshop. Dr. Hartmann then recognized Dr. Lester Shapiro, from Area II. Dr. Shapiro addressed the body and broached the subject of an approved action paper from the November 1991 Assembly meeting entitled, "Avoiding APA Conflict of Interest." He inquired whether there was a report on this paper. His request was referred to Ms. Jeanne Robb, Director, Office to Coordinate the Board and Assembly. Dr. Shapiro then spoke of another November 1991 paper on Industry Sponsored Symposia. This paper had been referred to the Scientific Program Committee. Dr. Sabshin addressed Dr. Shapiro's concern and noted that several Industry Sponsored Symposia had been turned down for the 1992 Annual Meeting due to topic and/or speaker overlap. Dr. Shapiro quoted a *Psychiatric News* article stating the financial connection between the APA Office of Education and Abbott Laboratories. Dr. Sabshin again addressed Dr. Shapiro's concerns and assured him that the monies obtained from Abbott Labs was through an educational grant and did not obligate APA or its Office of Education in any way to Abbott Labs. Lastly, Dr. Shapiro questioned the propriety of APA Past Presidents connected with the Industry Sponsored Symposia on anxiety sponsored by the Upjohn Company. Dr. Lawrence Hartmann addressed Dr. Shapiro's concerns and assured him that the connection was justified within the proper

context. Dr. Hartmann then recognized Dr. Jim Stringham from the Illinois Psychiatric Society, Area IV. Dr. Stringham proposed the creation of a task force to deal with anger, hostility, and resentment as they directly affect the work of psychiatrists today. Dr. Hartmann suggested that this action be presented to the President-Elect, Dr. Joseph English, in written form. Dr. English did make note, however, that there had been no formation of new components within the last year due to existing financial conditions. Dr. Hartmann stated that the Joint Reference Committee would address this issue again.

The Annual Business Meeting and Forum were adjourned by Dr. Hartmann at 1:30 p.m.

Opening Session

The opening session was called to order by Lawrence Hartmann, M.D., 120th President of the Association, on Sunday evening, May 3, in the Washington Convention Center. Dr. Hartmann read a letter of greetings to the membership from The Honorable Sharon Pratt Kelly, Mayor of the District of Columbia.

Dr. Hartmann introduced those seated on the stage with him: the members of the APA Board of Trustees, the officers of the APA Assembly, and Past Presidents of the Association. Dr. Hartmann then recognized members of the audience, including the members of the Assembly Executive Committee; Past Speakers of the Assembly; Past Vice-Presidents of the Association; newly elected APA national officers, trustees, and Assembly officers; presidents of the APA district branches; and the chairpersons of APA councils, commissions, and joint commissions. He then thanked the members of the Assembly for their hard work and dedication.

Allan Tasman, M.D., chairperson of the Scientific Program Committee, and Jeffrey S. Akman, M.D., chairperson of the Local Arrangements Committee, were introduced and thanked by Dr. Hartmann; each then presented a brief report.

Dr. Hartmann then thanked and recognized the following distinguished representatives of psychiatric and other related organizations from the United States and abroad:

Representatives of Organizations in the United States: Anne Alonso, Ph.D., President, American Group Psychotherapy Association; Sheila G. Baler, Ph.D., President, American College of Mental Health Administration; Kathryn E. Barnard, Ph.D., R.N., President, National Center for Clinical Infant Programs; Ruth Tiffany Barnhouse, M.D., President, Association of Women Psychiatrists; Allan Beigel, M.D., President, Group for the Advancement of Psychiatry; Harvey Bluestone, M.D., President, American Board of Forensic Psychiatry, Inc.; Jack W. Bonner III, M.D., President, National Association of Private Psychiatric Hospitals; Gordon H. Bower, Ph.D., President, American Psychological Society; Juan C. Cabrera, M.D., President, Philippine Psychiatrists in America; C. Robert Cloninger, M.D., President, American Psychopathological Association; Rabbi Jeffrey Cohen, D.Min., President, Association of Mental Health Clergy; Richard L. Cohen, M.D., President, American Academy of Child and Adolescent Psychiatry; Bertram Cohler, Ph.D., President, American Orthopsychiatric Association; Suzanne Dandoy, M.D., President, American College of Preventive Medicine; John B. Davies, M.D., President, American Society of Psychoanalytic Physicians; Prakash Desai, M.D., President, Na-

tional Association of VA Chiefs of Psychiatry; Michael R. Dillon, Ed.D., President, American Association on Mental Retardation; Marvin G. Drellich, M.D., President, American Academy of Psychoanalysis; Margaret Duff, President, American Psychiatric Association Auxiliary; David L. Dunner, M.D., President, Society of Biological Psychiatry; Paul Errera, M.D., Director, Mental Health & Behavioral Sciences Service Department of Veterans Affairs; Gerald H. Flamm, M.D., President, American Association of Psychiatric Administrators; Barry S. Fogel, M.D., Director, American Neuropsychiatric Association; Marshall Forstein, M.D., President, Association of Gay and Lesbian Psychiatrists; Frederick J. Frese, Ph.D., President, National Mental Health Consumers Association; Desmond S. Fung, M.D., President, Association of Chinese American Psychiatrists; Marc Galanter, M.D., President, American Academy of Psychiatrists in Alcoholism and Addictions; Alma Rose George, M.D., President, National Medical Association; Judith H. Gold, M.D., President, American College of Psychiatrists; Stanislaw Golec, M.D., President, Association of Polish Psychiatrists and Neurologists in America; Lillian Gonzalez-Pardo, M.D., President, American Medical Women's Association, Inc.; Frederick K. Goodwin, M.D., Director, National Institute of Mental Health; Enoch Gordis, M.D., Director, National Institute on Alcohol Abuse and Alcoholism; Frederick G. Guggenheim, M.D., President, Association for Academic Psychiatry; Irwin N. Hassenfeld, M.D., President, Association of Directors of Medical Student Education in Psychiatry; Adolph Herath, M.D., President, Sri Lankan Psychiatrists in America; Helen S. Hintz, President, National Depressive and Manic-Depressive Association; G. Richard Holt, M.D., M.S.E., President, American Academy of Otolaryngology - Head & Neck Surgery; Lucille Joel, Ed.D., R.N., President, American Nurses' Association; Dale Johnson, President, National Alliance for the Mentally Ill; Richard F. Jones III, M.D., President, American College of Obstetricians and Gynecologists; Irwin Kopin, M.D., President, American College of Neuropsychopharmacology; Robert L. Leon, M.D., President, American Association for Social Psychiatry; Alan I. Leshner, Ph.D., Deputy Director, National Institute of Mental Health; Constance E. Lieber, President, National Alliance for Research on Schizophrenia and Depression; Richard C. Lippincott, M.D., President, National Association of State Mental Health Program Directors; Don R. Lipsitt, M.D., President, American Association of General Hospital Psychiatrists; Willis C. Maddrey, M.D., FACP, President, American College of Physicians; G. Alan Marlatt, Ph.D., President, Association for the Advancement of Behavior Therapy; Peter A. Martin, M.D., President, Benjamin Rush Society; Robert J. McAllister, M.D., Ph.D., President, National Guild of Catholic Psychiatrists; Charles McCafferty, M.D., President, American Society for Adolescent Psychiatry; Morris B. Mellon, M.D., President, American Academy of Family Physicians; Ricardo P. Mendoza, M.D., President, American Association for Emergency Psychiatry; Richard A. Millstein, Acting Director, National Institute on Drug Abuse; Christine Mitchell, R.N., M.T.S., President, American Society of Law & Medicine; Marianne H. Mitchell, Ed.D., President, American Association for Counseling and Development; David L. Nimmo, J.D., President, National Council of Community Mental Health Centers; Bernard L. Pacella, M.D., President, American Psychoanalytic Association; Ashwin Pandya, M.D., President, American Association of Psychiatrists from India; Walter A. Pedemonte, M.D., President, American Society of Hispanic Psychiatrists; Ghulam Qadir, M.D., President, Pakistan Psychiatric Society of America; Kathleen M. Quinn, M.D., President, American Academy of Psychiatry and the Law; Anthony B. Radcliffe, M.D., President, American Society of Addiction Medicine; Roger N. Rosenberg, M.D., President, American Academy of Neurology; Elisabeth Rukeyser, Chairman of the Board, National Mental Health Association; Abdel Aziz Salama, M.D., President, Arab American Psychiatrists Association of America; Raymond Scalettar, M.D., Secretary-Treasurer, American Medical Association; M. Ali Shamie, M.D., President, Society of Iranian Psychiatrists in North America; Daniel W. Shea, M.D., President, American Academy of Pediatrics; G. Pirooz Sholevar, M.D., President, Society of Professors of Child and Adolescent Psychiatry; Alan P. Siegal, M.D., President, American Association for Geriatric Psychiatry; Peter M. Silberfarb, M.D., President, American Association of Chairmen of Departments of Psychiatry; Michael A. Representatives of Other International Organizations and Psychiatric Associations in Other Countries: Dr. Irving Philips, International Association of Child and Adolescent Psychiatry and Allied Professions; Dr. Sanford Finkel, International Psychogeriatric Association; Dr. Neal Cutler, International Association of Gerontology; Dr. Irene Jacob, International Society on the Psychopathology of Expression; Dr. Rodolfo Fahrner, InterAmerican Council of Psychiatric Organizations; Dr. Robert Pasnau, Pacific Rim College of Psychiatrists; Dr. A. Guilherme Ferreira, World Association of Social Psychiatry; Prof. Jorge Alberto Costa e Silva, World Psychiatric Association; Dr. Tim McKergow, Royal Australian and New Zealand College of Psychiatrists; Prof. Roger Montenegro, Argentine Psychiatrists' Association; Dr. Jacques Drouin, Canadian Psychiatric Association; Dr. Jiri Raboch, Czechoslovak Psychiatric Association; Dr. Fiona Caldicott, Royal College of Psychiatrists of Great Britain; Dr. C.R. Featherston, Canadian Psychoanalytic Society; Dr. Otto Doerr, Chilean Society of Neurology and Psychiatry; Dr. Roberto Chaskel, Colombian Society of Psychiatrists; Dr. Annette Gjerris, Danish Psychiatric Society; Dr. Carlos Leon Andrade, Ecuadorian Psychiatric Society; Prof. Ahmed Okasha, Egyptian Psychiatric Association; Dr. Antti Hemmi, Finnish Psychiatric Association; Prof. P. Cosyns, Flemish Association of Psychiatry and Neurology; Dr. Simon-Daniel Kipman, French Federation of Psychiatry; Prof. Uwe Henrik Peters, German Society of Psychiatry and Nervous Diseases; Dr. Felice Lieh-Mak, Hong Kong Psychiatric Association; Dr. Janos Furedi, Hungarian Psychiatric Association; Dr. Dadang Hawari, Indonesian Psychiatric Association; Dr. Charles Smith, Irish Division of the Royal College of Psychiatrists; Dr. Masahisa Nishizono, Japanese Psychoanalytic Association; Dr. Hajime Kazamatsuri, Japanese Society of Psychiatry and Neurology; Dr. Shigeru Kawasaki, Japanese Association of Psychiatric Hospitals; Dr. Dong-Il Kwak, Korean Neuropsychiatric Association; Dr. Chung Kyoon Lee, Korean Society of Biological Psychiatry; Dr. Charles Pull, Luxembourgian Association of Psychiatry; Prof. Frans G. Zitman, Netherlands Association for Psychiatry; Prof. Per Vaglum, Nordic Psychiatric Associations; Dr. Alv Dahl, Norwegian Psychiatric Association; Dr. Mohamed Chaudhry, Pakistan Psychiatric Society; Dr. Yuri Savenko, Independent Psychiatric Association of Russia; Dr. Lai H. Peh, Singapore Psychiatric Association; Dr. Ian Simon Fraser, Ministry of Health of South Africa; Dr. Somporn Bissaratid, Psychiatric Association of Thailand; Dr. Ruben Hernandez Serrano, Medical Federation of Venezuela; Dr. Antonio Pacheco Hernandez, Venezuelan Psychiatric Association.

APA Medical Director, Melvin Sabshin, M.D., introduced Dr. Hartmann, who gave the Presidential Address, "Reflections on Humane Values and Biopsychosocial Integration" (printed elsewhere in this issue of the *Journal*). Boris M. Astrachan, M.D., introduced Joseph English, M.D., President-Elect of the Association, who gave

the Response to the Presidential Address, "Patient Care for the Twenty-First Century" (printed elsewhere in this issue). Dr. Hartmann then adjourned the opening session.

Convocation

The 36th Convocation of Fellows was held in the Washington Convention Center beginning at 8:00 p.m. on Monday, May 4. Dr. Hartmann presided. After the processional march, Dr. Hartmann called the Convocation to order. President-Elect, Joseph English, M.D., then led the ceremony conferring Life Fellowship and the induction of Fellows of the Association.

Dr. Hartmann recognized the 1991 Corresponding Fellows: Leonardo A. Ancona, M.D., Rome, Italy; Ellis A.D. Busnello, M.D., Porto Alegre, Brazil; Char-Nie Chen, M.D., Shatin, Hong Kong; Hideo Hosaki, M.D., Tokyo, Japan; Simon-Daniel Kipman, M.D., Paris, France; Jochen E.F. Neumann, M.D., Ueckermunde, Germany.

The following 50-Year Life Fellows and Life Members (1942-1992) were then recognized: Freeman H. Adams, M.D., Stockton, CA; Justin H. Adler, M.D., Memphis, TN; C. Knight Aldrich, M.D., Charlottesville, VA; Herman S. Alpert, M.D., New York, NY; Louis Altman, M.D., Miami, FL; Herbert Jack Apfelberg, M.D., Palo Alto, CA; William C. Barger, M.D., Ft Lauderdale, FL; Frank R. Barta, M.D., Ocean Springs, MS; David Beres, M.D., Scarsdale, NY; Viola W. Bernard, M.D., New York, NY; Robert S. Berns, M.D., Los Angeles, CA; Irving Bieber, M.D., New York, NY; Walter R. Bonime, M.D., New York, NY; Morris V. Borenstein, M.D., New York, NY; Louis D. Boshes, M.D., Chicago, IL; Paul H. Brauer, M.D., New York, NY; S. George Brown, M.D., Milwaukee, WI; Howard B. Carscallen, M.D., London, ON, Canada; Stella Chess, M.D., New York, NY; Robert A. Clark, M.D., Elkins Park, PA; Joseph J. Doltolo, M.D., Brooklyn, NY; Maurice Dunn, M.D., Augusta, GA; Isaac C. East, M.D., Brandon, MS; Harmon S. Ephron, M.D., Fayetteville, NY; Knox H. Finley, M.D., Stinson Beach, CA; Joe E. Freed, M.D., Prosperity, SC; Moses M. Frohlich, M.D., Laguna Hills, CA; Samuel Futterman, M.D., Sebastopol, CA; Nicolai Gioscia, M.D., New York, NY; Leonard Gold, M.D., Stamford, CT; Charles Greenberg, M.D., Nyack, NY; John Howard Greist, M.D., Indianapolis, IN; William S. Hall, M.D., Columbia, SC; Lynwood Heaver, M.D., Tulsa, OK; Thomas V. Hoagland, M.D., Moore Haven, FL; John O. Hurt, M.D., Vinton, VA; William T. Hyslop, M.D., Traverse City, MI; Edward R. Janjigian, M.D., Kingston, PA; Edwin Kasin, M.D., New Rochelle, NY; S. Harvard Kaufman, M.D., Seattle, WA; Francis W. Kelly, M.D., Fairport, NY; James P. King, M.D., Radford, VA; Oscar Kozberg, M.D., Little Rock, AR; Harold J. Lawn, M.D., St. Paul, MN; Henry D. Lederer, M.D., West Chester, PA; Alexander H. Leighton, M.D., Halifax, NS, Canada; Robert J. Lentz, M.D., Laguna Hills, CA; Hans W. Loewald, M.D., New Haven, CT; Sydney B. Maughns, M.D., St Louis, MO; Michael Mendelson, M.D., Westbury, NY; Charles Samuel Mullin, M.D., Boston, MA; Thomas A. Naclerio, M.D., West Hempstead, NY; Richard W. Nelson, M.D., Worcester, MA; Leo Rangell, M.D., Los Angeles, CA; William Rottersman, M.D., Atlanta, GA; Jurgen Ruesch, M.D., San Francisco, CA; Bertram Schaffner, M.D., New York, NY; Manuel J. Scham, M.D., Yonkers, NY; Daniel E. Schneider, M.D., New York, NY; Julius Schreiber, M.D., Washington, DC; John P. Shovlin, M.D., Carbondale, PA; Werner Simon, M.D., Minneapolis, MN; S. Mouchly Small, M.D., Buffalo, NY; Stewart R. Smith, M.D., Brookline, MA; W. David Steed, M.D., Hinsdale, IL; Thomas W. Sugars, M.D., Bend, OR; John B. Train, M.D., Tamarac, FL; Ellsworth H. Trowbridge, Jr., M.D., Sun City, AZ; Walter I. Tucker, M.D., Wellestley, MA; Robert Joseph Van Amberg, M.D., Montclair, NJ; Bella S. Van Bark, M.D., New York, NY; Hewitt I. Varney, M.D., Annapolis, MD; Jack A. Vatz, M.D., Palm Springs, CA; George Leland Wadsworth, M.D., Waterloo, IA; Edward J. Weiss, M.D., New York, NY; Frederick L. Weniger, M.D., Pittsburgh, PA; Benjamin Wiesel, M.D., Hartford, CT; Isadore S. Zfass, M.D., Richmond, VA.

Dr. Hartmann then presented Honorary Fellows, Dr. Jean Endicott (in absentia), Mrs. Patricia Kind, and Dr. Rachel Gittelman Klein, and Distinguished Fellow, Dr. Leo E. Hollister, with their fellowship medallions.

Dr. Hartmann introduced The Honorable Edward M. Kennedy (D-MA), United States Senate. Senator Kennedy gave the William C. Menninger Memorial Convocation Lecture.

Special Presidential Commendations were presented to Leon Eisenberg, M.D., "in appreciation of his many decades of high intelligence, hard work, scientific skepticism, and social consciousness on behalf of children, public health and social policy"; to Erik H. Erikson (in absentia), "in appreciation for a generative lifetime of loving, working and playing; of science, art and wisdom"; to Jeanne Spurlock, M.D., "a tough and gentle inspiring colleague, and a good mother to children of all ages"; and to The Mental Health Law Project, "in recognition of its 20 years of advocacy and on the occasion its new name honoring Judge David L. Bazelon, a pioneer in the field of psychiatry and the law." This award was accepted by Mr. Leonard Rubenstein, Executive Director of the Project, and Mr. Richard Bazelon, son of Judge David L. Bazelon.

Distinguished Service Awards were presented to Albert J. Solnit, M.D., Commissioner of Mental Health for the State of Connecticut; and to Eli Robins, M.D., a faculty member of the Washington School of Medicine; and the Institutional Distinguished Service Award was presented to the American College of Neuropsychopharmacology, and was accepted by Roger Meyer, ACNP President-Elect. This award was established by the Board of Trustees in 1964 to honor APA members who have contributed exceptional meritorious service to American psychiatry, and to groups which have benefitted the APA, the field of psychiatry, or the mentally ill.

After introducing the chairpersons of the award committees, Dr. Hartmann presented the 1992 awards.

W. Walter Menninger, M.D., President, Chief Executive Officer and Chief of Staff of the Menninger Clinic in Topeka, Kansas, received the Administrative Psychiatry Award. Established in 1983, this award honors an APA member who is a nationally recognized clinician executive, whose effectiveness as an administrator of major mental health programs has expanded the body of knowledge of management in the mental health services delivery system, and whose effectiveness has made it possible for them to function as a role model for other psychiatrists.

The APA Award for Research in Psychiatry, formerly the Foundations' Fund Prize for Research in Psychiatry, the highest award for research given by the APA, was awarded to Judith H.L. Rapoport, M.D., Chief of the Child Psychiatry Branch of the NIMH.

The APA Award for Research Development in Hospital Psychiatry, given to honor outstanding contributions in hospital psychiatry research, was presented to Leona Bachrach, Ph.D., Research Professor of Psychiatry at the Maryland Psychiatric Research Center, University of Maryland School of Medicine.

The APA/Dista Products Resident Research Award, established in 1985 to honor a psychiatry resident for excellence in research undertaken during residency, was presented to Gianni L. Faedda, M.D., a psychiatry resident at McLean Hospital in Belmont, MA; to Glenn N. Saxe, M.D., a psychiatry resident at Harvard University Medical School at Massachusetts Mental Health Center/Massachusetts General Hospital; to Stephen M. Strakowski, M.D., the chief resident in the Psychiatric Disorders Program, Howard University Medical School; to J. Randolph Swartz, M.D., a psychiatry intern and resident at Harbor-UCLA Medical School; and to Debby W. Tsuang, M.D., a resident-in-training at the University of Iowa Hospitals and Clinics.

The APA/Wisniewski Young Psychiatrist Research Award, established in 1990 in honor of the late Dr. Alexander A. Wisniewski to recognize significant research accomplishments or promise of young psychiatrists, was presented to James T. McCracken, M.D., Assistant Professor of Psychiatry at the UCLA School of Medicine.

The Francis J. Braceland Award was presented to Harvey L. Ruben, M.D., Chairperson of the APA's Joint Commission on Public Affairs and host of the radio call-in show, "Talknet." This award was established in 1977 to honor a member of the Association who has made outstanding contributions as an author, spokesperson and publicist in the service of the mentally ill and disabled, and to the art and science of helping them.

The Marie H. Eldredge Award, established in 1964 to honor an APA member or resident residing and working in Hawaii, Pennsylvania, or New Jersey, and recognizing research work into the cause and treatment of neuroses and retardation, was presented to Duncan B. Clark, M.D., Assistant Professor of Psychiatry at the Western Psychiatric Institute and Clinic, University of Pittsburgh.

The Samuel G. Hibbs Award was presented to Evelyn Albrecht

Schwaber, M.D., Training and Supervisory Analyst at the Psychoanalytic Institute of New England, East, for her paper entitled "Psychoanalytic Theory and Its Relation to Clinical Work." This award is given for the best unpublished paper on a clinical subject.

The Human Rights Award was presented for the first time this year to the Science and Human Rights Program and the Committee on Scientific Freedom and Responsibility of the American Association for the Advancement of Science. The award was accepted by Robert Kirschner, M.D., Chairperson of the AAAS Committee on Scientific Freedom and Responsibility. This award was established in 1990 to recognize an individual or organization exemplifying the capacity of human beings to protect others from damage related to the professional, scientific, and clinical dimensions of mental health, at the hands of other human beings.

The Blanche F. Ittleson Award for Research in Child Psychiatry, given to a child psychiatrist or group of investigators for published results of research pertaining to the mental health of children, was presented to David B. Herzog, M.D., Associate Professor of Psychiatry, Harvard Medical School.

The Kempf Fund Awards for Research Development in Psychobiological Psychiatry were presented to Daniel C. Javitt, M.D., who was a resident in the Albert Einstein College of Medicine/Montefiore Medical Center combined program, and is now Assistant Professor, Department of Psychiatry and Neuroscience, Albert Einstein College of Medicine, to honor a resident who demonstrates exceptional promise in psychiatric research; and to Stephen R. Zukin, M.D., Professor, Department of Psychiatry and Neuroscience, Albert Einstein College of Medicine of Yeshiva University, to honor research excellence in the psychobiological, psychological, and/or sociological causes and treatment for the mental disease known as schizophrenia.

Saul I. Harrison, M.D., Professor Emeritus at the University of Michigan, received the Agnes Purcell McGavin Award, given to honor a psychiatrist who has done and is currently doing outstanding work related to the preventive aspects of the emotional disorders of childhood, through framing concepts, developing proofs or creating applications.

The Robert T. Morse Writers Award, which honors popular writers who have made major contributions to the public understanding of psychiatry and mental illness, was presented to Felice J. Freyer (in absentia), medical writer for the *Providence Journal-Bulletin*.

Dr. Paulos Mar Gregorios, an internationally known religious thinker and writer, and former President of the World Council of Churches, received the Oskar Pfister Award, given to honor outstanding contributions in the field of psychiatry and religion.

The Isaac Ray Award, given to those who have made outstanding contributions to forensic psychiatry or to the psychiatric aspects of jurisprudence, was presented to The Honorable Harry A. Blackmun, United States Supreme Court Justice since 1970.

The Robert L. Robinson Award was given to KOCO-TV staff in Oklahoma City: Jack Ahearn (in absentia), chief news photographer; Jane Braden, health reporter; Ann Parrington (in absentia), news photographer; and Gary A. Wolfe (in absentia), news photographer, for their outstanding work on the KOCO-TV "State of Mind" program; and to Catherine Olian (in absentia), producer, and Lesley Stahl (in absentia), Co-Editor, for "60 Minutes" for their outstanding work on the CBS News 60 Minutes "Prozac" program. The Robert L. Robinson Award recognizes radio and television (including cable) productions that contribute significantly to a better public understanding of psychiatry and mental illness.

The Arnold L. van Ameringen Award in Psychiatric Rehabilitation was presented to Arthur T. Meyerson, M.D., Professor of Psychiatry and Chairman of the Department of Psychiatry and Mental Health Sciences at the Hahnemann University School of Medicine in Philadelphia, for his outstanding contributions to the field of psychiatric rehabilitation, in the areas of clinical service, research, education, advocacy or a combination thereof.

The Seymour D. Vestermark Award, which recognizes an educator who has made outstanding contributions to undergraduate, graduate, or postgraduate education and career development in psychiatry, was presented to Carol C. Nadelson, M.D., Director of Training and Education for the Department of Psychiatry at the New England Medical Center in Boston and Professor of Psychiatry and Vice Chair of Academic Affairs at Tufts University School of Medicine.

The Jack Weinberg Memorial Award for Geriatric Psychiatry was

presented to Dan G. Blazer, M.D., Director of the Affective Disorders Program at Duke University Medical Center. This award honors a psychiatrist who has demonstrated special leadership or who has done outstanding work in clinical practice, training or research into geriatric psychiatry anywhere in the world.

After the presentation of these awards, Dr. Hartmann adjourned the Convocation.

Awards presented at meetings or sessions other than the Convocation included the following:

District Branch Newsletter of the Year Awards, given to recognize excellence in achievement and honor those newsletters and their editors that have most effectively communicated with the District Branch membership. The award for Large District Branches was presented to the *Massachusetts Psychiatric Society News*, Eileen B. Kahan, M.D., Editor; and to the *Wisconsin Psychiatrist*, Gilbert B. Tybring, M.D., and Richard J. Thurrell, M.D., Editors; and for Small District Branches, *SYNAPSE*, Robert N. Sobel, M.D., and Syed Abdullah, M.D., Editors. The Continuing Excellence Award was presented to *APS Action*, James F. Hooper, M.D., Editor; *Connecticut Psychiatrist*, Boris G. Rifkin, M.D., Editor; *Pennsylvania Psychiatrist*, Lee Miller, M.D., Editor; and the *Washington Psychiatric Society Newsletter*, Harold I. Eist, M.D., Editor.

The first annual Asian/Asian American Award was presented to Tsung-yi Lin, M.D., Honorary President of the World Federation of Mental Health, and to Lindbergh S. Sata, M.D., Chairman of the Department of Psychiatry and Human Behavior at St. Louis University. This award is given to recognize significant contributions toward understanding the impact and import of Asian cultural heritages in areas relevant to psychiatry, to encourage scholarship and research in culture-specific mental health issues and treatment needs of Asian populations and to stimulate scientific exchange on transcultural issues.

The Manfred S. Guttmacher Award, given to honor outstanding contributions to the literature of forensic psychiatry, was given to James C. Beck, M.D., Director of the Cambridge Court Clinic and Chief of Forensic Psychiatry at Cambridge Hospital.

The Lilly Psychiatric Research Fellowship was awarded to Shitij Kapur, M.D., a fourth-year resident in the Laboratory of Neuropharmacology at the Western Psychiatric Institute and Clinic, University of Pittsburgh. The fellowship was established to provide support for the career development of a postgraduate medical trainee who has shown exceptional promise in psychiatric research.

The Adolf Meyer Award honors outstanding investigators and was awarded to George L. Engel, M.D., Professor Emeritus of Psychiatry and Medicine at the University of Rochester in New York.

The Award for Patient Advocacy, which recognizes a public figure respected for personal accomplishments and beliefs, who has promoted the improvement of services for people coping with mental disorders and substance abuse, and who has fought stigma by speaking out about experiences with mental illness and psychiatric treatment, was awarded to Pulitzer Prize-winning author, William Styron.

The Benjamin Rush Award, which honors an individual who has achieved renown for his/her contribution to the history of psychiatry from that field or other fields such as medical history, anthropology or sociology, was awarded to Aaron Lazare, M.D., Chancellor of the University of Massachusetts Medical Center, Worcester.

The Simon Bolivar Award, which is given to honor a prominent Hispanic statesman or spokesperson, was awarded to Raquel E. Cohen, M.D., Professor of Psychiatry and Adjunct Professor of Pediatrics at the University of Miami School of Medicine.

Gloria Johnson-Powell, M.D., Professor of Child Psychiatry at the Harvard Medical School, received the Solomon Carter Fuller Award, given to honor a Black citizen who has pioneered in an area which has significantly benefitted the quality of life for Black people.

The Jacob K. Javits Public Service Award, which honors a public servant who has made a significant contribution to the cause of the mentally ill, was received by Minnesota State Representative Gloria M. Segal.

Scientific Sessions

The Scientific Program began on Monday, May 4, but continuing medical education (CME) courses and industry sponsored symposia began on Saturday and Sunday, May 2-3. There were 22 discussion

groups; nine forums; 122 symposia; 27 industry sponsored symposia; two special presidential symposia; 628 new research presentations; two debates; one "round table discussion"; 121 papers presented in 40 paper sessions; 172 workshops (including 58 APA component presentations and 114 issue); 15 film sessions; 32 videotape sessions and three video production clinics; 122 CME courses; four medical updates; five review of psychiatry sessions; four clinical case conferences; two, two-part continuous clinical case conferences; three "research consultation with . . ." sessions; and 11 "clinical consultation with . . ." sessions. Other sessions included "Research Advances in Psychiatry: An Update for the Clinician"; "Workshops on Private Practice Issues"; the residents' session, "Meet the Experts: Sunny-Side Up"; the ADAMHA Workshop; the DSM-IV Update; the Public Symposium; the Social Security Workshop; and an AIDS Education Program.

There were 31 lectures presented. The speakers, their current positions, and the titles of their presentations are listed here.

On Sunday, May 3, a lecture was given by James C. Beck, M.D., Director of the Cambridge Court Clinic, Chief of Forensic Psychiatry at Cambridge Hospital and Associate Professor of Psychiatry at Harvard Medical School, "The Death Penalty, Race and Psychiatry."

On Monday, May 4, the following speakers gave lectures: Evelyn Albrecht Schwaber, M.D., Training and Supervisory Analyst at the Psychoanalytic Institute of New England, East, "Psychoanalytic Theory and Its Relationship to Clinical Work"; Dr. Svetlana Polubinskaya, Senior Research Scholar in the Department of Criminal Law and Criminology of the Institute of State and Law of the Russian Academy of Sciences in Moscow, "From the USSR to the Independent States: Where the Former Soviet Psychiatry Will Go"; M. Scott Peck, M.D., author of the best-selling book, *The Road Less Traveled* and nationally recognized authority on the relationship between religion and science, "Biopsychosocialspiritual Psychiatry: What is Psychiatry to Do About Spirituality?"; Raquel E. Cohen, M.D., Professor of Psychiatry and Adjunct Professor of Pediatrics at the University of Miami School of Medicine and Director of the Children's Center of the Office of the State's Attorney in the 11th Judicial Circuit of Florida, "Twenty Years and Twenty Post-Trauma Clinical Lessons: From Macro Events to Micro Application"; Stanley J. Watson, M.D., Associate Director of the Mental Health Research Institute and Professor and Research Scientist in the Department of Psychiatry at the University of Michigan in Ann Arbor, "The Dopamine Receptor Super-Family and Its Implications for Psychiatry"; William Styron, 1968 Pulitzer Prize-winning author of *The Confessions of Nat Turner*, "Depression and the Creative Process"; Eric Lander, D. Phil., Associate Professor of Biology at the Massachusetts Institute of Technology and Director of the MIT Center for Genome Research, "Human Genetics and the Human Genome Project: Scientific and Social Implications"; Helmut Remschmidt, M.D., Managing Director of the Center of Neurology and Psychiatry and Director of the Department of Child and Adolescent Psychiatry at the Philipps-University in Marburg, Germany, "Research Fields and Strategies in Developmental Psychopathology"; Otto F. Kernberg, M.D., Associate Chairman and Medical Director of the New York Hospital-Cornell Medical Center, Westchester Division, and Professor of Psychiatry at Cornell University Medical College in New York, "Masochism: Psychopathology and Clinical Observations"; Senator Edward M. Kennedy, (D-MA), Convocation Lecture.

On Tuesday, May 5, the following lectures were given: Dr. Paulos Mar Gregorios, internationally known religious thinker and writer, and former President of the World Council of Churches, "Religious Masters as Psychiatrists: The Threefold Role of Religion in the Healing of Mind, Body and Soul in Society"; James A. McDermott, M.D., US Representative (D-WA), "Perspectives of a Psychiatrist in Congress"; Inge Kemp Genefke, M.D., founder and Medical Director of the International Rehabilitation and Research Centre for Torture Victims in Copenhagen, "Torture: A Threat to Democracy, a Challenge to Psychiatry"; Charles Krauthammer, M.D., Pulitzer Prize-winning syndicated columnist, "America and the New World Order: Trials of a Lonely Superpower"; Hugh L. Freeman, D.M., Honorary Professor in the Department of Sociology and Anthropology at the University of Salford, England, "Mental Health and the Environment"; Frederick K. Goodwin, M.D., Director, National Institute of Mental Health,

"Conduct Disorder as a Precursor to Adult Violence and Substance Abuse: Can the Progression Be Halted."

On Wednesday, May 6, the following lectures were presented: Carol C. Nadelson, M.D., Past President of the American Psychiatric Association, Director of Training and Education for the Department of Psychiatry at the New England Medical Center in Boston and Professor of Psychiatry at Tufts University School of Medicine, "Ethics, Empathy and Gender in Health Care"; Paula J. Clayton, M.D., Professor and Head of the Department of Psychiatry, University of Minnesota Medical School, "Reactive Depression: Its Place in the Classification of Affective Disorder"; W. Walter Menninger, M.D., President, Chief Executive Officer and Chief of Staff of the Menninger Clinic in Topeka, Kansas, "Critical Elements in Organizational Function"; Professor Leo Steinberg, Professor Emeritus of the History of Art, University of Pennsylvania, "The Devil His Due: Who's Who in Michelangelo's Creation of Adam"; Gloria Johnson-Powell, M.D., Professor of Child Psychiatry at Harvard Medical School and Director of the Camille Cosby Ambulatory Care Center of the Judge Baker Children's Center in Boston, "Black Monday's Children: A Multi-Cultural Agenda for the 21st Century"; Dr. Janine Chasseguet-Smirgel, a training analyst in Paris and author, "Eating Disorders and Femininity"; Louis Joylon West, M.D., Professor of Psychiatry, UCLA School of Medicine and Director of the Preventive Psychiatry Center at UCLA, "Psychiatry and Scientology"; Stanley I. Greenspan, M.D., Clinical Professor of Psychiatry and Behavioral Sciences and of Pediatrics at George Washington University Medical School in Washington, D.C., and Supervising Child Psychoanalyst at the Washington Psychoanalytic Institute, "The Formation of the Mind: Implications for the Prevention of Autism and Disorders of Thought and Affect"; Martin Duberman, Ph.D., Distinguished Professor of History at the Graduate School and University Center of the City University of New York, "Cured: A Gay Man's Odyssey in Psychotherapy"; Stephen Jay Gould, Ph.D., Professor of Geology and of Zoology at Harvard University and Curator of Invertebrate Paleontology at Harvard's Museum of Comparative Zoology, "A Wonderful Life: The Pattern of Life's History and the Improbability of Human Evolution"; George E. Mahy, M.B., Senior Lecturer in Psychiatry, Faculty of Medical Sciences, University of the West Indies, Cave Hill Campus, Barbados, "Suicide and Attempted Suicide in a Developing Country: The Case of Barbados."

The lectures presented on Thursday, May 7, were: Aaron Lazare, M.D., Chancellor of the University of Massachusetts Medical Center in Worcester, "Shame and Humiliation in the Clinical Encounter"; David Dressler, Ph.D., Lecturer in Neurobiology, Harvard Medical School, "Thinking About Thinking: Recent Molecular Biological Insights into Learning and Memory"; Paula Tallal, Ph.D., Professor of Neuroscience and Co-Director of the Center for Molecular and Behavioral Neuroscience at Rutgers University in Newark, New Jersey and Adjunct Professor of Neurosciences at the University of Medicine and Dentistry of New Jersey-New Jersey Medical School, "Neurobiological Foundations of Language Development and Disorders."

Other Activities

The Committee on Local Arrangements, Jeffrey S. Akman, M.D., chairperson, planned many activities, among which were golf and tennis tournaments, biking, and birdwatching. Some of the tours included: Monuments by Moonlight, Behind Closed Doors - Historic Georgetown, Embassy Row and Georgetown, Monticello, Enchantment by the Bay, and Behind the Scenes: The United States Capitol.

Meeting of the Board of Trustees

The Board of Trustees met in regular session on Sunday, May 3.

Meetings of the Assembly

The Assembly met on Friday, Saturday, and Sunday, May 1, 2, and 3.

STEVEN S. SHARFSTEIN, M.D.
Secretary, American Psychiatric Association

THE AMERICAN JOURNAL OF PSYCHIATRY

Editorial

Defining the Future in Medical Education

In its report (1), the Robert Wood Johnson Foundation's Commission on Medical Education has called for a shift in medical education to a degree that calls to mind the impact of the Flexner Report of 1910, which highlighted the importance of basic science for medical education. The Flexner Report encouraged the establishment of strong departments, each with responsibility for discrete blocks of the curriculum.

Much has transpired since the Flexnerian revolution. Most recently, especially in the last 10–15 years, biomedical science has exploded and flourished. Simultaneously, there is a "health quake" currently embracing the delivery and financing of health care. The Robert Wood Johnson Commission has set forth a blueprint for the education of physicians that takes cognizance of these fast-moving developments.

Psychiatry and behavioral science, which in past decades have had varying importance in the curriculum depending on the medical school, play an important role in the Robert Wood Johnson scheme, although they are integrated into the general education of physicians.

In fact, integration is a central concept in the Robert Wood Johnson template. The commission recognizes that overly sharp boundaries between some disciplines lead to teaching that is at variance with the increasing convergence, for example, of the basic sciences. Also, the commission report recognizes the need to teach "clinical problems in the context of advances in the basic sciences." The commission encourages teaching that emphasizes how we think and the interrelations among what we know rather than artificially compartmentalized knowledge.

The lessons taught by liaison psychiatrists and by professionals in the other behavioral disciplines have influenced the core of what the commission envisions for an acceptable medical education. One of the six recommendations in the report is for physicians to have "understanding of the behavioral and social aspects of health and disease." The report takes note of the fact that maladaptive behavior plays a major role in many illnesses and that behavior change is critical to health promotion and disease prevention. The commission views as untenable the dichotomy between psychosocial and biological factors in illness.

The report also calls for 1) an expansion in training settings to ambulatory care, nursing homes, hospices, etc., 2) evaluation that matches the educational goals of the faculty and is much more derivative of faculty consideration than a function of outside test making, and 3) establishment of an appropriate and well-positioned authority that oversees curriculum change and the quality of the medical education experience.

The report deals with many other aspects of medical education, including the emotional and moral fitness of medical students, the role of modern "informatics" in the learning process, clinical epidemiology, the need to make better use of the fourth year, and the importance of the process of learning for a lifetime career rather than simply preparation for specialty selection.

Clearly, the physicians of the future will face different customs of practice. They will be equipped with much more knowledge than those practicing today. Less autonomy, more accountability, lower incomes for some, more organized health care systems, more oversight, and more team involvement are all likely to characterize the

lives of the physicians of the 1990s and beyond. The commission suggests changes in education that will equip physicians to handle these challenges and to feel satisfaction that what they learn is consistent with the challenges of practice.

Central to the commission's report is the hope that physicians, in working as partners with better informed patients, will see their role not only as prescribers of the best therapeutic advice but also as professionals dedicated to doing all they can to bring about the best possible state of health and function for the patient. The doctor, it is hoped, will not be simply a Nobel laureate in conveying knowledge but also a model partner and advocate for the patient's and family's health and welfare.

Psychiatry has an important role in helping to make students observers of their own socialization into the profession. We should help foster the development of an attitude of caretaking and responsibility for the individual in the context of family, community, and population. This will involve more focus on observation by students of their mentors' and their own behavior as they learn to become physicians who are advocates for the patient, a goal of medical education that should be given more attention.

The Robert Wood Johnson Commission has set out a lofty intent. Simultaneously, the foundation has funded eight medical schools to implement models of such curriculum change.

Psychiatry, which often has lamented its role as outsider, may take satisfaction in the fact that many of its teachings are part of a central core of curriculum reform in this report. This is good news not only for psychiatrists but also for patients because it should lead to the emergence of a more sensitive, more responsive, and more comprehensively trained physician.

The Cost-Effectiveness of Psychotherapy: A Plan for Research

Janice L. Krupnick, Ph.D., and Harold Alan Pincus, M.D.

The authors assess gaps in the current knowledge base on psychotherapy research and the cost-effectiveness of psychotherapy. Despite the considerable and increasingly sophisticated body of research on the efficacy of psychotherapy, there is an alarming paucity of studies focusing on the cost-effectiveness of psychotherapy. This problem is particularly evident in the absence of studies exploring nonclinical effects of treatment and the broader range of domains in which intervention may have an impact. Initiation of research on the cost-effectiveness of psychotherapy is important for ensuring good clinical practice and data-based policy formulation. What is needed is greater specificity regarding the populations and problems for which psychotherapy can provide the greatest benefits, identification of the variables, measures, and methodological approaches that are most useful in yielding these important data, and comprehensive quantification of the costs and effects of psychotherapy.

(Am J Psychiatry 1992; 149:1295-1305)

The drive to contain health care costs makes critical the need to assess the efficacy and cost-effectiveness of various medical practices. In the case of psychotherapy, a sizable literature attests to its safety and efficacy (1-9), and, as demonstrated by the design of the increasingly imitated National Institute of Mental Health (NIMH) Treatment of Depression Collaborative Research Program (7), the present state of the art in psychotherapy evaluation has reached a high degree of sophistication. Little attention has been paid, however, to cost-effectiveness, particularly with reference to the broader range of societal effects.

The paucity of data in this area is puzzling given the

current economic climate and need for careful allocation of scarce resources. As the APA Task Force on Psychosocial Treatment Research observed, accountability in the practice of mental health care has been increasingly demanded by governmental bodies (J. Docherty, personal communication). If adequate research data are not provided, mental health services will be extremely vulnerable to additional budgetary constraints.

In drawing conclusions about alcohol abuse treatments, the Institute of Medicine (10) asserted that the present cost-effectiveness data are insufficient for unambiguous policy guidance, and Holder and Hallen (11) advised consideration of comparative cost-effectiveness in all investigations of treatment efficacy. Given the gaps in our current knowledge about the cost-effectiveness of treatments across the broader range of psychiatric disorders, these recommendations could be extended to any study investigating the impact of psychotherapy. The purpose of this paper is to emphasize the need to investigate the cost-effectiveness of psychotherapy, including the nonclinical effects of treatment, which frequently have been overlooked in previous studies. Our aim is to stimulate high-quality research in this area that might serve as a guide to clinical practice while providing the basis for informed policy and reimbursement decisions.

Received April 25, 1991; revision received Dec. 18, 1991; accepted Jan. 17, 1992. From the Department of Psychiatry, Georgetown University School of Medicine, Washington, D.C., and the Office of Research, American Psychiatric Association. Address reprint requests to Dr. Pincus, Office of Research, American Psychiatric Association, 1400 K St., N.W., Washington, DC 20005.

The opinions expressed in this paper do not necessarily represent the official policy of the American Psychiatric Association.

The authors thank the members of the APA Committee on the Practice of Psychotherapy, especially Marcia Goin and William Sledge, as well as Morris Parloff, Howard Goldman, Herbert Schlesinger, Steven Sharfstein, John Docherty, and Mardi Horowitz for their comments on this paper.

ECONOMIC COSTS OF PSYCHIATRIC DISABILITY

Both the prevalence and economic costs of psychiatric disability are enormous: in 1988 psychiatric illnesses affected almost one-third of the U.S. adult population, who fulfilled lifetime criteria for at least one alcohol, drug abuse, or other mental disorder (12), for an annual cost of approximately \$273 billion in 1988 dollars (13). In addition to the emotional pain and suffering caused by these disorders, they are major causes of nonpsychiatric illness, disability, and death in the United States, leading to the use of costly medical resources, major losses in productivity, motor vehicle accidents, and incarceration.

Severe psychiatric impairments account for 14%–20% of work disabilities in the United States, and 11% of the people receiving Supplemental Security Income or Social Security Disability Income (SSDI) have been judged mentally disabled (14). The annual cost of depression to our society was estimated in 1986 as approximately \$16.3 billion (15), while the annual cost of alcohol and drug abuse, described recently as posing a major threat to worker health and corporate profits, is \$134.1 billion (13).

It is also known that psychological stress frequently becomes manifest as nonpsychiatric conditions requiring costly workups and treatment. Epidemiologic studies show that patients with psychiatric disturbances often seek treatment at primary care sites for medically unexplained symptoms, make at least twice as many health care visits as comparison subjects (16), and experience longer hospitalizations, incurring greater costs than patients without psychiatric comorbidity (17). This is particularly evident among the elderly, who account for a disproportionate share of health care expenditures (18). Other studies show an average prevalence of major nonpsychiatric illness of 47% among psychiatric patients and death rates that are higher than for comparison subjects. Stone and Short (19) found that nearly one of every four informal caregivers must alter work hours or take unpaid leave to accommodate care for a disabled elder and behavioral problems are most responsible for the conflict between employment and caregiving.

Finding that 75% of the costs of depression can be attributed not to direct treatment but to lost social and economic productivity, Stoudemire et al. (15) stated that timely and appropriate treatment of patients would lead to substantial savings to society. Data suggest that various substance abuse programs are also cost-effective (20), although the findings are qualified by a paucity of cost-effectiveness studies and the absence of controlled trials. As Gerstein and Lewin (20) noted, since the benefits of treatment accrue to families, neighborhoods, and businesses, it is appropriate for the public, government, and business sectors to be concerned with providing treatment and assessing its efficacy.

COVERAGE OF PSYCHIATRIC SERVICES

Insurers and federal decision makers have been reluctant to cover psychiatric services, and American com-

panies, convinced that psychiatric costs represent "the single highest cost escalation" factor among health benefit offerings (21), increasingly have separated mental health and substance abuse benefits from other health coverage.

Despite this trend, recent findings (22) suggest that the increase in costs for most psychiatric services lags behind increases for nonpsychiatric medical care. Furthermore, S. Sharfstein (personal communication) believes that coverage might be modified if researchers could convincingly demonstrate the value of psychotherapy. He has observed, for example, that German national health insurance initially excluded coverage for psychotherapy but reinstated it when researchers demonstrated a reduction in medical costs associated with psychiatric intervention. Clearly, the process by which insurers, corporations, and the federal government make decisions about coverage is complex and multifactorial, and even with substantial, valid empirical data, success is not assured. Nonetheless, in the present policy environment, it is virtually impossible even to enter the decision-making arena without such data.

GLOSSARY

Any study on the cost-effectiveness of psychotherapy needs to operationalize terms such as "psychotherapy" and "cost-effectiveness." The APA Committee on the Practice of Psychotherapy (W. Sledge, personal communication) defined psychotherapy as "a method of treating mental disorders, the cornerstone of which is the development of experiential understanding of the meaning of symptoms and/or . . . those characteristic patterns that cause the patient to suffer limitations and pain. In contrast to somatic or pharmacological intervention, psychotherapy relies on verbal means and techniques to modify characteristic ways of thinking, feeling, and behaving that interfere with the patient's capacity for maximal functioning."

Cost-effectiveness analysis has been defined (23) as a technique that compares the costs and effects of a particular program or intervention in cases where the costs and effects are expressed with different measures. Costs are usually assigned a monetary value, but effects are often expressed in other units. This approach enables readers to make up their own minds as to whether the effects achieved by an intervention warrant its cost. This approach differs from cost-benefit analysis, which also compares the cost of interventions and resultant effects but expresses all costs and effects in the same units, usually monetary. Generally, two types of costs are examined in an economic assessment of a treatment: 1) direct costs, defined (13) as the actual dollar expenditures related to the illness or disorder, which include amounts spent for hospitalization, services of physicians and other medical professionals, drugs, appliances, and rehabilitation; and 2) indirect costs, defined (13) as the value of the productivity lost because of illness, disability, or injury. This includes the value of lost

work days and housekeeping days and lowered productivity due to illness or disability and losses due to premature death.

DESIGN ISSUES

Methodologically sound cost-effectiveness studies should use the same criteria as well-designed investigations of treatment efficacy (14). In emphasizing the need for studies that broadly assess the cost-effectiveness of psychotherapy across a full range of domains of potential effects, we encourage assessment of clinical, economic, personal, and societal change, including consideration of at least the following variables.

Population

While diagnostic homogeneity and well-specified study groups are part of any methodologically sound investigation, there is disagreement as to the most productive specific population to study. Should study subjects be persons with the more common psychiatric disorders, such as major depressive disorder, panic disorder, and agoraphobia, or groups that are the most costly to society in monetary and/or social terms?

For example, there is evidence that family therapy may be cost-effective for patients with schizophrenia, a population that is extremely costly in terms of hospital charges, family burden, and SSDI payments. Spencer et al. (24) found that female patients in a poorly functioning schizophrenic group who received family therapy did significantly better in general role functioning than patients who did not have this treatment, while Falloon et al. (25) found that family therapy combined with pharmacotherapy reduced the rate of relapse and length of hospital stay in schizophrenic patients whose families had high levels of expressed emotion.

Psychotherapeutic treatment for individuals with alcohol abuse has been shown to reduce the use of medical care, sick time, and time lost from work because of injuries (26), and opiate-dependent patients who received psychotherapy had significantly more or larger gains than those who received only drug counseling (27).

Another population of interest is caregivers, e.g., for the severely mentally ill or individuals with dementia. Data reported by Brodaty and Gresham (28) show that intensive intervention for the caretakers of patients with dementia can reduce the psychological morbidity of the caregiver and delay placement of the patient in a costly institution without increasing the use of health services by either patient or caregiver.

Despite clinical biases against psychotherapy for older persons (29), studies indicate not only the efficacy but also the cost-effectiveness of psychotherapy with older adults. Thompson et al. (30), in their investigation of psychotherapies for the depressed elderly, found this group to be an underserved population that could be helped by psychotherapeutic intervention. Furthermore, Mumford et al. (31) found that adults over the

age of 55 had a greater reduction in medical service utilization after mental health treatment than younger adults, and Morisky et al. (32) reported that education and support for patients' hypertension had a more positive influence on compliance among the elderly than among younger patients.

Another potential focus is individuals who seek non-psychiatric medical treatment, since there is evidence that psychotherapy can serve as a cost-benefit adjunct to treatments of these conditions. For example, Jacobson et al. (33) observed a decrease in hospital admissions for patients with diabetes who had participated in a family-oriented teaching program. Furthermore, as demonstrated in the Rand Medical Outcomes Study (34), there is a high rate of concurrent mental disorders in persons with general medical illnesses, which might interfere with compliance and morale in efforts to treat the medical illness. On the basis of the available information, it is reasonable to assume that adding psychotherapy in a targeted way to the overall medical treatment package could improve the efficacy of the other treatment approaches and reduce disability.

Another issue is whether to focus on axis I or axis II disorders. When investigators rely on symptom-based formulations, patient clusters include those who are symptomatically similar but may be quite different on a number of dimensions that relate more to social functioning, e.g., level of developmental maturation, presence or absence of a personality disorder. Some experts (e.g., M. Horowitz, J. Docherty, personal communications) suggest that a population which might be important to study is individuals with more severe character pathology, e.g., those in the narcissistic to borderline personality range, who are often high users of psychiatric benefits.

Type of Psychotherapy

The type of psychotherapy assessed should depend on the population selected for treatment. For patients with schizophrenia, the data suggest that family treatment, including behavioral components such as problem solving and goal attainment, may be useful. Behavioral therapy, which was found to be useful and cost-effective in a clinical trial of phobic subjects and persons with obsessive-compulsive disorder (35), has also been used in the treatment of alcoholism. Matching individuals with alcohol problems to particular treatments seems to increase the average effectiveness of therapy (10), but no cost-effectiveness data are available.

Treatment packages combining psychotherapy and medication, e.g., interpersonal psychotherapy and antidepressants for depressive disorders (36) or family therapy and antipsychotic medication for schizophrenia, are obvious candidates for study. Treatment approaches such as these not only reflect common clinical practice but also provide an opportunity to study the potential interactive effects of combined therapies.

A serious difficulty in interpreting the results of many studies is the lack of specificity in describing the treat-

ments used. What is actually practiced when a particular treatment approach is used may vary considerably across practitioners, and this variation discourages reimbursement. The extent to which a treatment method can be described and operationalized contributes to the degree to which it can be standardized. The advent of manual-guided treatments and the use of audiotapes and videotapes, which can be reviewed by experts, help in clarifying whether the prescribed treatment is actually being practiced, an important advance in assessing whether a particular type of treatment is clinically potent and cost-effective for a particular type of disorder. It should be noted, however, that even the use of a manual does not guarantee the skill with which the therapy is practiced. Further standardization of treatment procedures and additional clarification of what to do when and with whom would advance the field by making the treatments more testable and identifying more clearly what has actually been done in psychotherapy.

Recent studies of clinically depressed patients have compared dynamic or interpersonal therapies with cognitive, behavioral, or cognitive-behavioral treatments. The advantages of these therapies are that they are commonly practiced, that interpersonal therapy and cognitive-behavioral therapy were specially developed to treat depression, and that these last two treatments are carefully described in detailed manuals, which facilitate assessment of the degree to which the therapist adheres to the prescribed method. It has been argued (37) that standardized treatments based on psychiatric diagnoses are conceptually incompatible with currently practiced models of psychotherapy. Also, these methods have been assessed in only a limited number of contexts, and it is unclear how generalizable such techniques may be to psychiatrically disturbed patients in nonpsychiatric settings (38). In spite of these caveats, however, we feel that the use of standardized techniques and methods, especially when adherence and competency are assessed, is a major advance in enabling researchers to more clearly determine which types of treatments work for given categories of patients.

It should be noted that some types of psychotherapy, by their very nature, lend themselves more easily than others to systematic investigation. For example, it may be easier to document change in behavior therapy, where progress can be charted on the basis of observable behavior, than in psychoanalysis or psychoanalytically derived psychotherapy. We are not suggesting that such treatments should not be studied but are simply pointing out that, given existing measures, it may be more difficult to find significant effects in investigations of some treatments than in others.

Length of Treatment

The optimal length of treatment for particular patient groups in terms of both efficacy and cost-effectiveness remains to be determined. One review of alcoholism treatments (10) suggested that, when indiscriminantly applied, interventions with more than brief durations

may have little additional benefit. In contrast, Andrews and Harvey's meta-analysis of 81 studies of core mental disorders (39) indicated that increased duration of therapy is associated with greater efficiency. The additional costs of longer-term treatment remain virtually unanalyzed, however, and there has been no examination of whether these costs are exceeded by benefits. Perhaps we need to better assess what changes take longer to achieve and whether those changes are worth the increments in resources involved in longer-term treatments. We also need to further distinguish the disorders for which longer-term therapy would be cost-effective.

Although the study of longer-term treatments adds considerable complexity and may involve a greater expenditure of research dollars, the available research data demonstrate not only that the study of longer-term work is feasible but also the importance of this issue, since the most costly mental disorders are chronic or recurrent. For example, in the treatment of patients with schizophrenia, Hogarty et al. (4) found that although good treatment effects were achieved with psychosocial interventions during 2 years of treatment, relapse rates rose rapidly when treatment stopped. On the basis of their data, these researchers recommended using strategies that could sustain compliance with maintenance psychosocial programs and pharmacotherapy over time. In their study on the role of the therapeutic alliance in the treatment of schizophrenia, Frank and Gunderson (40) found that patients who formed good alliances with their therapists achieved better outcomes after 2 years with less medication than patients who failed to establish good alliances, but the development of a therapeutic alliance was difficult and usually took at least 6 months to achieve. They noted that the patients who remained in their study groups made substantial gains; the longer they stayed, the more gains they made.

In depression research it has become clear that relapse is common after the termination of psychopharmacological or psychotherapeutic intervention. Addressing this problem in a 3-year randomized maintenance trial of patients with recurrent depression, Frank et al. (5) found that monthly sessions of interpersonal therapy could lengthen the time between episodes of depression. In a maintenance study of bulimic patients who responded to initial treatment, Pyle et al. (41) also documented a high (30%) relapse rate during the 6 months after initial treatment was completed. On the basis of a meta-analysis of the length of treatment and patient benefit, Howard et al. (42) concluded that it takes at least 26 sessions for the majority of patients to show some improvement from psychotherapy. They suggested that, on average, the maximum percentage improvement takes approximately 52 weekly sessions, depending on the patient's particular characteristics—some patients require fewer sessions and some require more.

Despite clinical assertions that greater therapy frequency leads to greater efficacy, there has also been little research on the benefit of more frequent psychother-

apy sessions (43). It would be useful to determine empirically whether greater therapy frequency leads to better clinical, and more cost-effective, outcomes than do less frequent sessions and whether there are particular disorders for which more frequent sessions are required to produce the desired results.

Type of Clinician

Research data (44) and clinical experience show that some therapists have more successful outcomes than others; for instance, trained psychotherapists achieve more successful results than primary care physicians who provide routine medical care (35), and more experienced therapists do better than novices (45). Since therapists with the most extensive training and experience are usually the most expensive, however, the question arises of what type of therapist with what degree of posttraining experience is most cost-effective.

McLellan et al. (46) found that the therapist's ability to 1) form a helping alliance and 2) adhere to the therapeutic technique are important determinants of effectiveness. Yet it is not clear whether these skills result from preexisting interpersonal strengths or clinical training. The ability to identify and interpret transference issues is more common in more highly skilled and experienced clinicians. However, how much training and clinical experience are necessary to offset the additional direct costs of the services of more senior therapists?

There is a clear movement in the field to develop competency criteria in order to assess a therapist's capacity to participate in treatment studies (47, 48). Methods have been developed and used to assess competency in various treatments and therapists' ability to adhere to the guidelines of a particular approach (48-50). Since these methods and measures are in their infancy, however, it would be useful to obtain data from additional studies at different sites to further assess the amount of additional instruction necessary to train even experienced clinicians in a specific method and to delineate the safeguards that need to be built in to ensure that therapists are adhering to the prescribed techniques.

Although investigators could reduce the costs of their studies by relying on psychiatric residents or graduate students to provide treatment, results from studies using inexperienced clinicians may not have as much impact. It is generally assumed that for the best test of a procedure, it needs to be applied by someone who is schooled and experienced in its application. For this reason, certain levels of postgraduate training and experience are considered essentials in the selection of competent therapists. These also should be people who are well-versed and experienced in the particular treatment method they will apply and who have confidence in the efficacy of their method. The advantages of using experienced therapists have been demonstrated in the review by Rounsaville et al. (48) of findings from manual-guided training programs in interpersonal therapy, which showed that experienced therapists who had been trained in dynamic therapy were able to achieve a

high level of competency in interpersonal therapy after comparatively brief training and were able to maintain adherence to the manual over the course of a long study.

Treatment Context

Although inpatient treatment is expensive and the need for hospitalization is often used as an indicator of poor outcome (27), hospitals may be the most effective setting for certain populations. Whether inpatient or outpatient therapy is more cost-effective may depend to a considerable extent on the nature of the patient population studied. For example, in a prospective study of 40 inpatients with borderline personality disorder, Tucker et al. (51) found that after 6 to 24 months of hospitalization, patients experienced a marked decline in self-destructive behavior and a significant improvement in family relationships. In contrast, Stein and Test (52, 53) found that use of a community-based program instead of hospitalization enhanced patient adjustment and produced substantial savings for a group of chronic patients, most of whom were suffering from schizophrenia.

For the treatment of alcoholism, some individuals may fare better in residential programs than in outpatient settings, namely, those with less social stability and those with dysfunctional family or work relationships (54). Other studies (26), however, show that outpatient or day treatment settings offer treatment that is at least as good as, if not better than, the treatment offered in inpatient or residential settings.

Another question is whether some patients are more effectively served in general medical settings, as opposed to specialty psychiatric settings, given the finding from recent epidemiologic studies (16) that most patients with mental illness are seen exclusively in primary care sites. There are, however, questions about the quality of care currently received by patients with mental disorder in the primary care sector (55, 56). While situating a study at a primary care site may facilitate assessment of the degree to which psychiatric intervention can affect overall health care utilization, it would be important to control for such variables as the nature and quality of care and the particular characteristics of the study group. For example, Blackburn et al. (57) noted differences in the effects of cognitive therapy and pharmacotherapy between hospital outpatient clinics and general practice clinics, and they observed that different patient populations sought treatment at the different sites.

With the growth and expansion of employee assistance programs, the work setting increasingly has been seen as an appropriate place for mental health intervention. Employees who are unable or unwilling to take time off from work to consult mental health professionals may be willing to seek out or accept services in the workplace. Because of the ease of workplace services, employees may seek help earlier in problem development, so this locale may be a potential resource for pre-

vention. Treatment at work sites may permit collection of important data regarding links between psychotherapy and effects on work.

A wide variety of treatment settings offer different treatment packages. Should one approach be, as H. Schlesinger (personal communication) has suggested, comparison of different treatment packages in different settings to determine which is most cost-effective? In addition, there is the issue of extricating specific treatments from an overall "package" provided in a particular setting, e.g., "inpatient care," although this is not a problem if the focus of assessment is the package.

Outcome Measures

An important task in designing a study on the cost-effectiveness of psychotherapy is identification of the outcomes of greatest interest and the measures that could most sensitively assess these variables. Appropriate and adequate evaluation of what may be derived by a course of psychotherapy is of particular concern given the problems of third-party reimbursers with claims for certain forms of psychotherapy (58). A third area of concern is the identification of methods by which to assign monetary values to the various outcomes.

The multiple spheres of interest in psychotherapy outcomes can generally be situated within two main categories: clinical outcomes and functional outcomes. Clinical outcomes deal primarily with psychiatric and physiological signs and symptoms and can be assessed by using symptom measures and/or assessments of general health care use. Functional outcomes pertain to changes in social role functioning as a result of psychotherapy. Some areas of interest regarding functioning in the workplace might be absenteeism (i.e., number of sick and injury days), worker turnover, job loss, productivity, earnings, and morale. Functioning as a student might involve class attendance, grades, and graduation. Marital satisfaction questionnaires and rates of marital separation and divorce might measure conjugal behavior.

It is important to assess not only the patient who has received psychotherapy but also the people whom that individual influences. For example, how the individual is functioning as a parent might be reflected in how the person's offspring are functioning personally, socially, and academically. The level of caretaking and productivity of family members also could be assessed. Other areas of concern might be the degree to which the individual is contributing to or drawing resources from the community. What involvement has the person had with social service agencies and the legal system before and after psychotherapy? What has been the nature and extent of social service and legal involvement? Has the individual been able to provide emotionally and financially for spouse, children, and/or ill or aging parents? Have child care or institutional services been used because of psychological disabilities? What measures might most efficiently help collect these data?

The final step in cost-benefit research is the translation of clinical and functional data into economic terms.

The issues here include how to assess the losses to an organization caused, for example, by absenteeism or psychiatric disability. What methods are most appropriate for assigning a monetary value to social costs, such as the cost to a community of dropping out of school, teenage pregnancy, or poor parenting? How can measures designed to assess clinical and functional behaviors be adapted to economic calibration?

Among questions to consider in this domain are the following: Do we have adequate measures for assessing social costs and are the existing measures sensitive enough to address the less tangible aspects of social functioning? Would it be useful to encourage development and refinement of methods that would enable investigators to measure more effectively the more psychologically subtle and yet important dimensions of outcome in economic terms?

Work Productivity, Creativity, and Satisfaction

In a literature review on the effects of psychiatric treatments on work restoration, Mintz et al. (14) concluded that "although there is a vast literature on psychiatric treatments, relatively little is known about the specific effects of treatments for specified conditions on the functional capacity to work" (p. 2). This view was supported by Riejhaber and Goldbeck (59), who noted that although ignored emotional problems are exceedingly costly in terms of medical utilization and a plethora of other consequences ranging from absenteeism and lowered productivity to vandalism and violence, employee assistance managers have failed to keep cost data for their mental health programs separate from their total health cost information.

Some attempts have been made, however, to assess the efficacy and cost-effectiveness of employee assistance or emotional health programs within organizations. These do not represent methodologically sound, controlled investigations, but they provide promising exploratory data. For example, 60% of employees who received up to 10 sessions of insight-oriented or cognitive-behavioral therapy through an emotional health program at Equitable Life Assurance Society (60) said that the services they received were very helpful in terms of the presenting problem and job attendance, performance, and satisfaction. For employees with stress-related disorders, for every dollar invested in the program there was a \$5.52 return on that investment in terms of increased productivity per person per year, although it was not clear how these figures were calculated.

In a study of the effects of mental health intervention on 12 out of 37 alcoholic employees who were enrolled in a Kennecott Copper Corporation program for an average of 1 year (61), the absentee rate decreased by 50%, sickness and accident costs decreased from \$70.67 to \$25.33 per month, and medical/surgical costs decreased from \$109.04 to \$59.91 per month. The employees who were categorized as alcoholic but did not receive treatment worsened in all categories.

In an American Telephone and Telegraph employee as-

sistance program providing crisis intervention (62), 86% of the treated subjects were considered "rehabilitated" or "improved" after treatment; rehabilitation was defined as "restoration to a former state of health and efficiency." In terms of job performance, before treatment 76% were rated poor, 17% were rated fair, 7% were rated good, and 0% were considered excellent; after treatment, 79% were rated as good or excellent and 36% were rated excellent. Comparison of 22-month periods before and after treatment showed that days of absence were reduced from 421 to 92, and occasions for absence declined from 172 to 35. There was a significant reduction in disability absences, from 1,531 days of disability before treatment to 192 days after treatment. Of 44 employees referred to the employee assistance program who were in known job jeopardy, 40 retained their jobs, saving the company \$84,000 in job training for new employees.

Although the association between psychotherapy for troubled employees and increased attendance, and perhaps increased productivity, has been made in these studies, the studies themselves are highly problematic because of severe limitations in study design. There is a notable lack of specificity in delineating who the subjects were, what disorders they suffered from, what the treatments were, who administered them, and for how long and in what context they were received. Also, since many of these reports were published by the companies that offered the services, the degree of investigator bias is unclear.

Moreover, it is not clear that appropriate measures of work productivity, creativity, and satisfaction exist. The work subscale of the Social Adjustment Scale and the Quality of Well-Being Scale may be two useful assessments in this domain, but they do not seem adequate for the entire task because it is important to ascertain not only the individual subject's assessment of his or her own productivity and creativity on the job but also assessments by other key figures, such as employers or supervisors. Furthermore, do we have adequate operational definitions of such constructs as "productivity" and "creativity"? Are there measures of functioning in these domains? Of the measures that do exist, can they provide assessments from different perspectives? It would not be difficult to construct a job satisfaction scale, but would this provide information on capacity, productivity, and creativity? Furthermore, is it possible to translate greater work effort and increased ingenuity (if these are assets to the business) into monetary value? Work restoration is not the only aspect of work functioning with financial implications. Which specific aspects of work should be included in a cost-effectiveness assessment of psychotherapy? Should aspects such as the quality of job performance be included, and if so, is there a valid and reliable way to make judgments in this area?

Ability to Attend School or Graduate

School attendance and completion are similar in many respects to work restoration and functioning. At

the lowest level of quantification are the simple issues of whether a student attends classes and graduates. More subtle issues are attitudes toward schooling, school adjustment, functioning, and morale. What are the direct and indirect costs of dropping out of school? Whose school adjustment should be assessed—only individuals who receive treatment or also family members, whose ability to attend and function in school may be affected by a patient? What is the relationship between school failure and other social problems, such as crime, substance abuse, teenage pregnancy, and reliance on Aid to Families With Dependent Children? On an even more subtle level, is there a way to quantify the cost to society of an individual's failure to maximize his or her educational potential?

Ability to Care for Family

If psychotherapy is successful, one would expect its recipients to gain an increased capacity to nurture others functionally, financially, and psychologically. If it increases the ability to secure and maintain employment, financial strains on the family should be reduced. If it helps to keep a parent out of the hospital, the costs of child care are eliminated or reduced. If it increases the capacity of a caretaker to keep a mentally ill family member in the home because of a greater ability to handle stress, the costs of institutionalization may be reduced. Some questions here may be related to how one operationalizes a concept such as "ability to care for the family." Should this be based strictly on the capacity of the individual to provide food and lodging for dependents, without requiring outside help to do so, or can qualitative judgments involving the quality of care also be included? Can this be expressed in monetary terms?

Marital Satisfaction

There is evidence that psychotherapy can produce improvements in family functioning and adaptive coping (63), but there are no data regarding the monetary cost of marital dissolution and the degree to which psychotherapy might reduce those costs. S. Sharfstein (cited in reference 64) reported a sixfold increase in medical utilization in the year following marital breakup, although S. Budman et al. (unpublished 1980 paper), comparing groups of individuals who received group therapy versus no therapy after marital separation, found that the experimental subjects were less distressed after treatment but did not utilize health care services significantly less. However, detecting offsets in medical costs in areas where there is already a rich provision of services is difficult. Furthermore, what are the costs of family disintegration beyond medical utilization? It has been shown (65) that the income of divorced women and children falls substantially in the years following a divorce. Does this translate into a greater need for social services? What are the increases in legal fees and court costs for settlement disputes and custody battles? What is the cost of psychiatric services

for spouses and children who are traumatized by the disruption and the parents' diminished capacity to nurture their children in the years following divorce (66)?

Health Care Costs and Utilization

The primary focus of cost-effectiveness research on psychotherapy has been the impact on health care utilization. A number of studies have confirmed the economic advantage of using psychotherapeutic services, particularly in producing offsets in medical costs. For example, in a meta-analysis of 34 studies, Mumford et al. (67) found that relatively minor interventions for people who recently had suffered heart attacks or were facing surgery had large effects in speeding recovery and shortening hospital stays. Schlesinger et al. (68) showed that individuals who had at least seven sessions of psychotherapy after the diagnosis of one of four chronic diseases used 66% fewer medical services during the third year after treatment than a no-therapy group with the same diseases. In a study of myocardial infarction survivors (69), the survival rate for those who had undergone 12 months of group therapy was 10% higher than the survival rate for the no-therapy group and 19% higher when only severe cases were considered. In a review of 22 studies, Jones and Vischi (70) found a mean reduction of 34% in medical care utilization after mental health intervention and a mean reduction of 45% after participation in alcoholism programs. In three studies of health maintenance organizations (71), medical utilization rates declined for psychotherapy patients who initially had been high medical service users. Jameson et al. (72) estimated that inclusion of outpatient psychotherapy benefits reduced monthly medical costs by \$9.41 per patient.

These pioneering studies suggest the cost-effectiveness of psychotherapy and provide a solid foundation on which to build, but basing current policy decisions on them is problematic, since many were conducted more than a decade ago, before considerable advances in research methods delineating psychotherapy and improvements in diagnosis and assessment. In addition, there is now disagreement as to the best ways to assess medical utilization and the role of this variable in assessing the overall cost-effectiveness of psychotherapy. Some investigators use medical claims to assess utilization, while others feel that this approach does not assess the degree of offset with enough precision. Some investigators (e.g., H. Schlesinger, personal communication) feel that the existing work on the medical cost offset of psychotherapy is adequate and that formulations can be drawn, while others have raised questions about the utility of the approach to cost-effectiveness research used in previous studies. For example, although Levitan and Kornfeld (73) assessed the cost-effectiveness of providing a liaison psychiatrist for hip fracture patients on an orthopedic unit and showed a shorter length of stay and lower hospital costs in the liaison group than in the no-liaison group, Lyons et al. (74) argued that although the liaison group

had a shorter length of stay, no attempt was made to ensure that this did not merely indicate premature discharge. In reviewing the study by Schlesinger et al. (68) on the impact of mental health treatment on medical care utilization for patients with one of four chronic diseases, Lyons et al. (74) cited three major problems: 1) the treatment and no-treatment groups were not necessarily equal in severity of illness, 2) the effectiveness of the interventions was not studied, and 3) utilization of services is not synonymous with need for services. Given the further clarification of issues and refinements in methodological techniques that have occurred since the early studies were conducted, it seems that new investigations could add to and update existing data. The recent replication by Strain et al. (75) of Levitan and Kornfeld's hip fracture study involved major improvements in design and methodology and demonstrated important savings in medical care costs.

Given serious national concerns about current health care expenditures, the impact of psychotherapy on medical costs is certainly not an area to overlook. It is not, however, the only area of interest or importance. We are not critical of the existing literature per se but see it as too narrow in focus. Exploring cost-effectiveness exclusively in terms of the offset in medical care costs may trivialize mental disorders, and it narrowly defines the potential societal cost savings of psychiatric treatment.

Social Costs and Social Service Utilization

As discussed earlier, some of the more substantial changes that result from psychotherapy may be more in the social rather than medical realm of functioning, and yet there has been little investigation of these effects. Might psychotherapy decrease not only health care costs but also social care costs? Can it lead to a reduction in the use of social services, and if so, which ones and to what extent? Can psychotherapeutic services reduce criminal activity? If so, which could then in turn reduce police, legal, and court costs?

It is important once again to consider the effects of psychotherapy not only on the individual receiving treatment but also on family members and caregivers, whose own levels of mental health and social functioning may be seriously affected by the demands of an emotionally disabled dependent. What are the clinical and functional outcomes for caregivers when they or people who depend on them receive psychotherapeutic help? As Brodaty and Gresham (28) demonstrated, it is not only the identified patient but also the caregivers for that person who may suffer psychological morbidity because of the emotional and perhaps physical demands of their role. When caregivers "burn out," suffering psychiatric or social disability themselves, tax-supported social services often must be employed. Thus, the well-being and social efficacy of these individuals have cost implications for the rest of society. How do we measure the monetary value of the services of such individuals and the savings to the family and

society when their coping abilities are supported and sustained?

BARRIERS TO RESEARCH

In addition to the practical problems of conducting any research, two potential problems are particular to this area: identification of who would carry out this type of investigation and determination of whether the tools exist for carrying it out effectively.

Are there sufficient numbers of investigators with both the interest and competence to conduct this type of research? Would it be sufficient to create interdisciplinary teams, bringing in researchers from psychiatry, psychology, and health economics, or would it be advisable to create training opportunities, possibly in the form of postdoctoral research fellowships, to train specific individuals in the methods of conducting cost-effectiveness studies in psychotherapy and other mental health treatments?

As M. Kamlet (personal communication) has observed, measurement in this area involves some thorny issues, including the limitations of existing measures. For example, it may be possible to obtain qualitative descriptions of such domains as marital relations, friendships, and work productivity, but can these areas be measured adequately in quantitative terms? Kamlet asserts that while there exists at least one scale in this area (Kaplan's Quality of Well-Being Scale), measurement is not quantified in the way that an economist would approach it. In calibrating scores on these types of measures, economists may see numerical scales as arbitrary and the meaning of one score relative to another as unclear. Thus, there may be serious difficulties in translating psychiatric data into economic terms. Another question is whether there are adequate instruments for measuring "softer" areas of functioning, such as worker morale and the relationship between such variables as morale and productivity. Most investigators have shied away from dealing with variables that are so difficult to measure, yet focusing only on easily quantifiable variables means that a good deal of the richness of psychotherapy's benefits is overlooked.

SUMMARY AND RECOMMENDATIONS

A large body of existing data, including numerous meta-analyses of psychotherapy efficacy (1, 39) and critical findings on schizophrenia (4), depression (36), and anxiety (9), indicates that psychotherapy has substantial power to alleviate extraordinarily destructive and painful illnesses. It is becoming increasingly apparent, however, that those who advocate improved reimbursement for psychotherapy will have to make a strong case not only for its interpersonal and social benefits but also for its monetary benefit to policymakers, employers, payers, and the public. The existing data on the cost-effectiveness of psychotherapy indicate

that 1) little current research activity relates to this area; 2) previous studies have been narrow in scope, are few in number, and have had substantial methodological limitations; and 3) important design and measurement issues need to be carefully considered.

Investigations stimulated by a series of workshops sponsored by NIMH and APA (76) demonstrate that quantification in the area of cost-effectiveness of mental health services is feasible. After these research development workshops, which were aimed at stimulating outcome research in consultation-liaison psychiatry, 12 grant proposals on the cost-effectiveness of these services were submitted to NIMH for scientific review, and six of these were funded.

What is needed is greater specificity regarding the populations and problems for which psychotherapy can provide the greatest benefits. More research also is needed to identify the variables, measures, and methodological approaches that are most useful in yielding these important data. Of most concern is the paucity of studies that attempt to quantify the costs and effects of psychotherapy in a comprehensive manner, producing results which can be used by researchers, policymakers, and the public. High-priority issues include the following.

1. Advancing the state of the art in cost-effectiveness analysis (77) by developing and/or modifying methods to make it more applicable to psychotherapy and more comprehensible to policymakers in this arena.

2. Gathering and assessing existing instruments for measuring psychotherapy-related change, as Waskow and Parloff (78) did in 1975, to assist investigators and to determine whether the instruments needed to conduct this type of investigation exist.

3. Supporting methods development aimed at creating and/or refining outcome instruments for cost-effectiveness studies that include assessment of nonclinical outcomes.

4. Encouraging the routine inclusion of cost data in all psychotherapy outcome studies in order to begin to define the relative cost-effectiveness of various psychotherapy treatments for specific disorders.

5. Expanding federal and other research funding of studies aimed at discovering the costs and effectiveness (across the broad range of domains) of different treatment approaches.

6. Providing training opportunities for clinical researchers with a career interest in developing and refining methods for studying the cost-effectiveness of psychotherapy.

It is only by facilitating and supporting well-designed cost-effectiveness research that we may learn the full role that psychotherapy can play in reducing human suffering and the long-term social and economic costs of mental illness.

Panic Disorder in Children and Adolescents: A Review

Donna Moreau, M.D., and Myrna M. Weissman, Ph.D.

***Objective:** Panic disorder has been considered an adulthood disorder that does not occur in children or adolescents. The authors' goals were to critically review the available evidence for panic attacks and/or panic disorder in children and adolescents, to review the limited data on the biological basis of panic disorder as it has been studied in children and adolescents, to discuss the possible treatment approaches for panic disorder in children, and to suggest potential opportunities for further research on panic disorder in children. **Data Collection:** Sixty-three articles pertaining to panic disorder in children and adolescents were critically reviewed. These articles included retrospective histories of adults with panic disorder, clinical case reports of children and adolescents with panic disorder, studies of psychiatrically referred children and adolescents, reports from epidemiologic community and school samples of children and adolescents, studies of children and adolescents at risk for psychiatric disorder, reports of panic-like symptoms in pediatric patients, family studies of panic, studies of the biological basis of panic in adults, and studies of treatment for panic. **Findings:** There is strong evidence that panic disorder occurs in children and adolescents and that its clinical presentation in this population is similar to that found in adults. **Conclusions:** Extending the many adult studies of panic disorder to children and adolescents would be extremely fruitful. Like adults with panic disorder, many children and adolescents are brought to emergency and medical clinics for the physical symptoms of unrecognized panic disorder.*

(Am J Psychiatry 1992; 149:1306-1314)

Although anxiety symptoms are common in children of all ages and both sexes (1), only three anxiety disorders (overanxious disorder, separation anxiety disorder, and avoidant disorder) are classified specifically as disorders of childhood. Family studies and retrospective reports of childhood symptoms by adults with anxiety disorders suggest a continuity between childhood and adult anxiety disorders. Early childhood histories of separation anxiety disorders in adults with panic disorder have been reported (2). Other studies have linked an early history of separation anxiety disorder to several other adult anxiety disorders such as generalized anxiety disorder and agoraphobia (3, 4) as well as a predisposition to other types of psychopathology (3). Panic disorder, however, has been considered a disorder of adulthood that does not occur in children or adolescents. There is now evidence sup-

porting the occurrence of childhood panic attacks with symptoms that are qualitatively distinct from those of separation anxiety disorder.

Isolated panic attacks occur in about 10% of adults, and recurrent panic attacks not meeting full diagnostic criteria occur in about 3.6% of adults (5). The rate of full-blown panic disorder is smaller (1.6%). There is increasing evidence that panic attacks and panic disorder are seriously disabling conditions with high morbidity (6-8). Moreover, a childhood onset of these disorders may be especially impairing. A report from the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) study (8) indicated that panic disorder with first onset at age 17 or younger was associated with greater risk of alcohol abuse, suicidal thoughts, suicide attempts, and use of emergency rooms than onset at age 18 or older.

Several retrospective reports from adults of their age at onset of panic attacks (9-12) have appeared, suggesting that panic attacks begin in childhood. However, before 1987 there were no published cases of panic attacks or panic disorder based on direct studies of children. In 1987, Casat et al. (13) reported the case of a 12-year-old girl with separation anxiety disorder and mitral valve prolapse. The girl reported symptoms suggestive of adult panic disorder, including tachycardia, sweating, dyspnea, generalized weakness, and "butter-

Received May 22, 1991; revision received Dec. 27, 1991; accepted Jan. 24, 1992. flies" in her stomach accompanied by school refusal. She later developed fears of crowds, heights, strangers, and being alone. Casat et al. suggested that some children with separation anxiety disorder may develop agoraphobia and panic attacks in adulthood. In 1989, three separate reports of panic attacks and/or panic disorder in a total of 24 children appeared (14-16).

In addition to retrospective reports of adults with panic disorder and clinical case reports of children and adolescents with panic, further evidence that panic attacks and/or panic disorder occur in children and adolescents can be found in clinical case reports of treatment of panic in children and adolescents, in assessments of psychiatrically referred children and adolescents based on structured diagnostic interviews and *DSM-III* criteria, in reports from epidemiologic community and school samples of children and adolescents, in studies of children and adolescents at risk for psychiatric disorders by virtue of their parents' psychiatric disorder, and in reports of panic-like symptoms in children and adolescents seen in pediatric services.

The purposes of this paper are 1) to critically review the available evidence for panic attacks and/or panic disorder in children and adolescents, 2) to review the limited data on the biological basis of panic disorder as it has been studied in children and adolescents, 3) to discuss the possible treatment approaches for panic disorder in this population, and, finally, 4) to suggest potential opportunities for further research on panic disorder in children and adolescents.

REVIEW OF THE LITERATURE

Retrospective Reports of Adults With Panic Disorder

In several studies of adults with panic disorder (9-12), the subjects retrospectively reported that their panic disorder began in childhood or early adolescence (figure 1). These reports have received little attention. Sheehan et al. (9) studied 100 patients 19-61 years old who had *DSM-III* panic disorder with agoraphobia. The range of age at onset of panic was 5-58 years; the mean age at onset was 24.1 years. Twenty-six patients reported experiencing symptoms before the age of 20 years: 12 were between 15 and 19 years old, 10 were between 10 and 14 years old, and four were younger than 9 years old. Of interest and concern is the fact that the mean time from onset of symptoms to treatment for the total sample was 12.7 years.

Breier et al. (11) reported on age at onset of panic disorder in 60 adults with agoraphobia, mixed phobia, and/or panic disorder diagnosed according to Research Diagnostic Criteria (RDC). Seventeen (28%) of these patients reported that their panic disorder began before they were 20 years old. Eleven patients (18% of the sample) reported that their first panic attack occurred between the ages of 10 and 17, three (5%) reported that their first panic attack was at age 18, and another three (5%) reported that their first attack was at age 19.

FIGURE 1. Retrospective Reports of Age at Childhood Onset of Panic

On the basis of a retrospective chart review of 62 adults with *DSM-III* panic disorder without agoraphobia whose mean age at onset was 26.6 years (range=5-51), Thyer et al. (12) reported that 38% of the patients experienced symptoms before the age of 20 and 11% experienced symptoms before the age of 10. Thyer et al. obtained similar results in 95 adult patients diagnosed with panic disorder and agoraphobia.

The NIMH ECA study (17), which included a probability sample of more than 18,000 subjects 18 years old and older living in five U.S. communities, found a peak onset of panic disorder between the ages of 15 and 19. More than 18% of the adults in this study reported experiencing panic before they were 10 years old, and an additional 7% reported experiencing panic between the ages of 10 and 15.

Klein et al. (18) reexamined their data on childhood panic attacks and panic disorder in two study groups: 343 consecutive admissions to an adult anxiety disorders clinic and 560 first-degree relatives of patients admitted to an anxiety disorders clinic. Using the data from structured diagnostic interviews administered by trained clinicians, they determined that nine (1%) of the 904 subjects reported experiencing spontaneous panic attacks before they were 13 years old. Klein et al. reviewed the narrative summaries of these nine subjects and concluded that only three of them gave reports consistent with four-symptom spontaneous panic attacks occurring in childhood. They pointed out the inherent problems in the validity of retrospective reports of panic and suggested that the definition of spontaneous panic "is best done in the context of a series of such attacks."

Although these reports suggest that panic disorder occurs in children and adolescents, retrospective reports of their childhood by adults are subject to problems of recall such as distortion and revision in addition to the validity issue raised by Klein et al. (18). In addition, prepubertal status at the time of onset of panic in

TABLE 1. Case Reports of Panic Disorder in Children and Adolescents

the subjects who retrospectively reported childhood onset was not established in these studies. Therefore, direct assessment of children and adolescents with panic disorder is critical to further our understanding of this disorder in this population.

Case Reports of Children and Adolescents

There are case reports of panic disorder in 22 children and adolescents that support adults' retrospective reports of their age at onset of panic disorder (14, 19-23) (table 1). Because many children with panic come from families with panic, the recognition of the child's disorder may represent a selection bias because parents with panic disorder may be more likely to recognize the symptoms in their children. Even though most of these studies did not use a structured diagnostic interview and cannot provide rates because of sampling problems, they are of interest because the diagnoses were made by experienced clinicians who provided details of the clinical phenomena.

These preliminary reports provide directions for future research based on sound methodology: use of structured diagnostic interviews, direct interviews with the child and the parent, and assessment of referred as well as nonreferred populations.

Vitiello et al. (19) made the first such report in a letter to the editor in 1987. They diagnosed *DSM-III* panic disorder in two prepubertal boys, one inpatient and one outpatient, using a structured diagnostic interview. The boys had been referred for separation anxiety. Their symptoms included shortness of breath, palpitations, chest pain, paresthesia, and trembling. Both boys had developed agoraphobia and school refusal. A family history of panic disorder was found in both children.

Biederman (20) reported panic disorder in three prepubertal children, two boys and one girl. Symptoms included restlessness, muscle tension, palpitations, sweating, and dry mouth in one boy; multiple autonomic symptoms in the girl; and symptoms of fear and shaking in the other boy. Two of the children refused to attend school, and the mothers of two of the children had a history of agoraphobia. Clonazepam was used successfully in all three children to reduce anxiety, and the children's functioning returned to normal.

Ballenger et al. (14) reported on three children, two girls and one boy, who had *DSM-III* panic disorder with ago-

raphobia, all of whom responded to alprazolam and imipramine. Symptom complexes varied for each child but included dizziness, tingling, trembling, shortness of breath, palpitations, and a cold and clammy feeling. A family history of panic was reported in one child.

Black and Robbins (21) described six adolescents with panic disorder, two boys and four girls. Only one of these adolescents reported prepubertal onset of panic disorder. Symptoms included hyperventilation, flushing, sweating, shortness of breath, dizziness, tachycardia, and paresthesia in most of the subjects and isolated symptoms of shaking, headaches, faintness, and palpitations in all of the subjects. All six subjects reported a history of depression. A family history of panic disorder with agoraphobia was reported in one adolescent. Four of the children responded favorably to desipramine or imipramine.

Vitiello et al. (22) also reported *DSM-III-R* panic disorder in six prepubertal children, five boys and one girl, referred to an academic child psychiatry service. All but one of the children were outpatients. All of these children had heart pounding, weakness, trembling or shaking, and feelings of dying or going crazy. Five children had shortness of breath, lightheadedness or dizziness, and chest tightness or pain. Four children had tingling of fingers or face, feelings of choking or smothering, and sweating. None of the children reported hot or cold flashes or blurred vision. School avoidance was diagnosed in three of the children. The diagnoses of separation anxiety disorder and school avoidance were independent of panic disorder. The mean interval between first panic attack and diagnosis was 3 years. A family history of panic disorder was found in all six children.

In a letter to the editor, Black et al. (23) reported on two additional prepubertal girls with panic disorder and agoraphobia. The diagnosis in both children was based on a structured diagnostic interview of the child and the parent. The 8-year-old girl had mild depressive symptoms and developed separation anxiety disorder subsequent to her panic disorder. Her father had a history of panic disorder with agoraphobia. She described sudden onset of fear accompanied by sweating, a "funny feeling in my throat," a "funny smell," trembling, nausea, feeling hot, her "heart feeling funny," and fear of loss of control. The 12-year-old girl reported onset of panic at age 9. Her attacks were char-

TABLE 2. Reports of Panic Disorder in Psychiatrically Referred Children and Adolescents

Study	Year	Sample	N	%	Subjects With Panic			Subjects With Coexisting Separation Anxiety	
					Age Range (years)		Boy:Girl Ratio	N	%
					At Time of Report	At Onset			
Alessi et al. (24)	1987	61 inpatients	10	16	14-17	12-15	4:6	4	40
Alessi and Magen (25)	1988	136 inpatients	7	5	7-12	3-12	4:3	6	86
Last and Strauss (26)	1989	177 outpatients	17	10	14-18	9-18	6:1	2	12

acterized by "sudden onset of extreme fearfulness, crying, breathlessness, dizziness, flushing, sweating, tachycardia, palpitations, tremulousness, feeling that she may lose control, nausea, headache, feeling a lump in the throat, and pleading with her parents to take her away from whatever situation they were in." There was no significant morbidity or family history of anxiety disorder. Both children were reported to respond favorably to tricyclic therapy. Despite the presence of a "funny smell" in the list of symptoms for one of these children, the authors did not consider the possibility of temporal lobe epilepsy. However, this girl's positive response to tricyclic therapy favors the diagnosis of panic.

Although these reports are of interest because of their clear clinical descriptions of panic in children, they suffer from sample bias and lack of structured or semistructured diagnostic interviews. In addition, in the absence of data from placebo-controlled trials, these reports of treatment efficacy must be considered tentative.

Assessment of Psychiatrically Referred Children and Adolescents

Diagnoses of panic disorder have been made in studies of psychiatrically referred children and adolescents using the Schedule for Affective Disorders and Schizophrenia—Childhood Version and *DSM-III* criteria (24-26) (table 2). The subjects were referred for psychiatric treatment for multiple reasons, not necessarily panic symptoms, and thus provide some limited data on the frequency of panic in psychiatrically referred children and adolescents.

Alessi et al. (24) found that 10 of 61 adolescents on an adolescent psychiatric inpatient unit had panic disorder according to RDC and that another 15 had possible panic disorder. All but one of the 10 patients with definite panic disorder had a comorbid depressive disorder. The mean age at onset of panic was 13.9 years, and no prepubertal onsets were reported. More than half of the adolescents with definite panic disorder reported symptoms of sweating, trembling, palpitations, and feelings of faintness. Trembling was reported by nine of the adolescents with panic disorder.

Alessi and Magen (25) diagnosed panic disorder in seven of 136 children consecutively admitted to a child diagnostic and research inpatient unit. Four of the chil-

dren with panic disorder were boys and three were girls. The most common referral symptoms were school refusal and aggression, followed by depression and somatic complaints. Trembling or shaking, dyspnea, palpitations, and dizziness were reported by five of the children with panic disorder, and chest pain, choking, faintness, fear of dying, hot and cold flashes, and sweating were reported by three. Paresthesias were reported in one child. Depressive disorders were diagnosed in four of the children.

Last and Strauss (26) reported that 10% of 177 consecutive referrals to an outpatient pediatric anxiety clinic had *DSM-III-R* panic disorder. Only one prepubertal child had panic attacks, and only one adolescent reported a prepubertal onset of panic. Panic symptoms resembled those found in the adult disorder. Palpitations/tachycardia, trembling, and flushes or chills were each reported in 94% of the patients with panic disorder, shortness of breath and sweating by 82% and dizziness/faintness by 75%. All other panic attack symptoms, except choking, were present in more than half of the children with panic disorder. Comorbidity was found in approximately half of the children, most commonly another anxiety disorder. Of interest is the fact that 33% of the mothers met *DSM-III-R* criteria for a lifetime diagnosis of panic disorder.

Again, the issue of prepubertal status was not specifically addressed in these studies. The age range of the children and adolescents (7-18 years), however, suggests that at least some of these children were prepubertal at the time of their panic.

Epidemiologic Community and School Surveys of Children and Adolescents

There have been no large, multisite epidemiologic surveys of children and adolescents using current psychiatric diagnostic criteria comparable to the ECA data on adults. Three small epidemiologic studies have reported on panic disorder (16, 27, 28) (table 3).

Hayward et al. (16) reported that the lifetime prevalence rate of at least one four-symptom panic attack in 95 ninth-grade students whose mean age was 14.5 years was almost 12%. Eight girls and three boys had panic disorder. Three other boys reported limited symptom panic attacks.

TABLE 3. Epidemiologic Surveys of Panic in Children and Adolescents

Study	Year	Sample	Instrument	Subjects With Panic	
				N	%
Hayward et al. (16)	1989	95 ninth graders	Structured Clinical Interview for DSM-III-R Disorders, panic disorder section	11	11.6
Macaulay and Kleinknecht (27)	1989	660 children in the community	Panic Attack Questionnaire	88	13.3
Whitaker et al. (28)	1990	356 high school students	Columbia Clinics Interview	2	0.6

Macaulay and Kleinknecht (27) surveyed 660 children and adolescents 13–18 years old. They found severe panic with symptoms similar to adult panic disorder in 30 of the subjects and moderate panic in 58 of the subjects. Severe panic included symptoms of distress and seriousness, but moderate panic referred to either distress or seriousness. There was no significant difference in frequency of attacks between subjects with severe and moderate panic. Girls outnumbered boys by about three to one. The median age at onset of panic was 13 years.

In a two-stage epidemiologic survey of a New Jersey community, Whitaker et al. (28) initially screened 5,000 students 14–17 years old for multiple psychiatric symptoms, including panic symptoms. During the second stage of the study, 356 students were interviewed with a semistructured interview yielding *DSM-III* diagnoses. The interviews were conducted by individuals who were blind to the results of the first stage of the study. A diagnosis of panic disorder was made on the basis of results from the Columbia Clinical Interview (29). The lifetime prevalence rate of panic disorder reported—0.6%—is similar to that reported in persons with onset at age 17 or younger in the ECA. Fewer than half of the students with panic disorder in the study of Whitaker et al. had received treatment for their symptoms.

The Whitaker et al. study used semistructured interviews, albeit before the development of validated semistructured *DSM-III* interview protocols suitable for use with children and adolescents. The other two studies used self-report questionnaires, and only Hayward et al. (16) had the diagnosis confirmed by a child psychiatrist using *DSM-III-R* criteria. *DSM-III-R* criteria were used to make a diagnosis of panic attacks, but the frequency of attacks was not reported so the diagnosis of panic disorder could not be confirmed. Despite these limitations, these data clearly support the occurrence of panic attacks in children and adolescents and support the high probability of such attacks meeting *DSM-III-R* criteria for panic disorder.

Studies of Children and Adolescents at Risk for Psychiatric Disorder

We reported on the occurrence of panic disorder in children at risk for psychiatric disorder by virtue of depression in one or more parents (15). Six (2.7%) of the 220 children in this study met *DSM-III* criteria for

panic disorder. A seventh child, who was 9 years old, reported panic attacks that did not meet the frequency criteria for *DSM-III* panic disorder. Diagnoses were made by a child psychiatrist and were based on all available information, including structured diagnostic interview of child and mother. The range in age at onset of panic disorder in this study was 5–18 years. Two of the six children with panic disorder were clearly prepubertal (they were 5 and 6 years old) at onset of panic. The prepubertal status at onset of panic of three of the children, who were 10, 12, and 13 years old, was not determined. Comorbid illnesses were common among the six children, particularly major depression and separation anxiety disorder. The symptom pattern of the panic attacks resembled that of the adult disorder. All six children reported shortness of breath, and five children reported palpitations. Chest pain, choking, dizziness, sweating, trembling, fear of death, faintness, and feelings of unreality were found in three of the children. Two children experienced tingling, and one child described hot and cold flashes. The parents of four of the children had panic disorder in addition to major depression.

Reports of Panic-Like Symptoms in Children and Adolescents Seen in Pediatric Services

Children with depressive disorders have been shown to have frequent somatic complaints (30, 31). Although there are many reports in the literature on childhood hyperventilation, the relationship of hyperventilation to panic attacks is unknown (32). Four studies in the pediatric medical literature (33–36) suggest the occurrence of panic attacks in children and adolescents (table 4).

Herman et al. (33) examined Mayo Clinic records over a 25-year period and found 34 children diagnosed with hyperventilation syndrome whose symptoms were suggestive of panic attacks. When these children were contacted for follow-up information, many reported chronic anxiety. van Winter and Stickler (34) reported panic disorder in six children at the Mayo Clinic. Herskowitz (35) reported on four children with panic attacks who were brought to pediatric services with neurological symptoms.

In a retrospective chart review of all cases seen between 1984 and 1988 by the psychiatric consultation-liaison service at a tertiary referral pediatric hospital, Garland and Smith (36) diagnosed four cases of *DSM-*

TABLE 4. Reports of Panic-Like Symptoms in Children and Adolescents Seen in Pediatric Services

Study	Year	Study	Subjects With Panic-Like Symptoms	Age Range at Onset (years)	Diagnosis
Herman et al. (33)	1981	Retrospective chart review of clinic patients	34	6-18	Hyperventilation syndrome
van Winter and Stickler (34)	1984	Case reports of clinic patients	6	9-17	Panic disorder
Herskowitz (35)	1986	Case reports of clinic patients	4	9-16	Panic attacks
Garland and Smith (36)	1990	Retrospective chart review of hospital patients	4	8-15	Panic disorder

III-R panic disorder. Three children were referred to psychiatry after months of medical workups yielding no organic etiology for somatic complaints. Substantial complications in the children's school and family functioning were noted. The authors suggested that children with the somatic complaints of panic disorder may be brought to pediatric services. If confirmed, this would be comparable to the situation for adults with panic disorder, who often seek medical rather than psychiatric treatment (37).

The Nature of Panic in Children and Adolescents

Some investigators question whether the nature of panic is similar in children and adults. Acute, sudden onset of physiological symptoms and the attribution of such sensations to losing control or going crazy seem to be necessary for a diagnosis of panic attacks. Nelles and Barlow (32), on the basis of Piaget's theory of cognitive development, expressed doubts as to whether children have the cognitive capacity to make such an attribution. The studies reviewed here (13-16, 18-28, 34-36) suggest that children experience the same physiological symptoms of panic as adults and also, like adults, attach fearful or catastrophic significance to these physical sensations. These fears and physical sensations do not seem to be invariably associated with or brought on by separation from a major attachment figure. Therefore, they appear to be distinct from separation anxiety disorder, which, in any event, is characterized by somatic complaints, not physiological symptoms suggestive of autonomic hyperactivity. Further detailed clinical study of the symptom pattern of children with panic disorder is needed.

Family Studies of Panic

Several studies have examined rates of anxiety disorders in the relatives of adults with anxiety disorder (38-41). Other studies have examined the rates of these illnesses in the relatives of children with anxiety disorders (42). A review of these and other studies in progress supports the familial nature of panic disorder (43).

To our knowledge, only one study has reported on the rates of anxiety disorders in the relatives of children with a diagnosis of *DSM-III-R* panic disorder. Last et al. (44) compared the rates of anxiety disorders in the first- and second-degree relatives of children 5-18 years old who had anxiety disorders (including panic disorder)

with rates of anxiety disorders in the first- and second-degree relatives of children who had attention deficit disorder and were never psychiatrically ill. Diagnoses of anxiety disorders were made in 94 children on the basis of results obtained from the Schedule for Affective Disorders and Schizophrenia for School-Age Children (KIDDISADS) (modified for *DSM-III-R*) administered to the child and the parent. Adult relatives of 94 children with anxiety disorders, nine of whom had a primary diagnosis of panic disorder, were given the Structured Clinical Interview for *DSM-III-R* and the childhood disorders sections (separation anxiety disorder, overanxious disorder, attention deficit disorder, avoidant disorder) of the modified KIDDISADS. The child relatives of the children with anxiety disorders were given the complete modified KIDDISADS. First-degree relatives of children with anxiety disorders had higher rates of anxiety disorder than first-degree relatives of two control groups. More specifically, the relatives of children with overanxious disorder had higher rates of panic disorder than the relatives of children with separation anxiety disorder and other anxiety disorders. There was a trend for relatives of children with panic disorder to have higher rates of panic disorder than relatives of children with other anxiety disorders. The small number of family studies that included children limit conclusions and suggest a potentially interesting area for further research.

DATA ON THE BIOLOGICAL BASIS OF PANIC IN CHILDREN AND ADOLESCENTS

There have been considerable research efforts in adults to identify potential biological markers for panic. Catecholamine levels, frequency of mitral valve prolapse, and agents that produce laboratory models of panic attacks have been studied. The latter include lactate infusion, carbon dioxide inhalation, isoproterenol hydrochloride, yohimbine hydrochloride, and caffeine, which can produce panic attacks in laboratory subjects with a history of panic disorder. These invasive challenge tests are used in research studies exploring the biological differences among anxiety disorders and the physiological basis of panic attacks (45). Therefore, their use in children for research purposes has been necessarily limited.

There has been some suggestion of an association between mitral valve prolapse and panic attacks in adults.

Both disorders can present with similar symptoms mediated by hyperactivity of the autonomic nervous system. The diagnosis of mitral valve prolapse is made by cardiac auscultation, which reveals a characteristic mid- to late-systolic click and/or late systolic murmur, and by echocardiogram. The prevalence of mitral valve prolapse in the general population is 3% to 4% (46). Women are more commonly affected than men. Age appears to affect the prevalence of mitral valve prolapse; children have rates of 1% and adolescents show rates approaching those found in adults (46). Mitral valve prolapse diagnosed by echocardiogram has been associated with panic disorder in adults in several studies (47–50) but not in others (51–53).

The literature on a possible association between mitral valve prolapse and anxiety in children is sparse. In a study of 813 children 9–14 years old, Arkfen et al. (54) found that the prevalence of mitral valve prolapse diagnosed by cardiac auscultation was 4.2%. These authors found no difference in anxiety scores between a group of children with mitral valve prolapse and a group of children without mitral valve prolapse. In an unpublished study Gorman and Klein (personal communication) found that mitral valve prolapse was diagnosed by echocardiogram in three out of 16 children with anxiety disorders, the majority of whom had separation anxiety disorder. The possible co-occurrence of mitral valve prolapse and panic disorder in children warrants further exploration based on these findings. We are currently conducting such a study at our institution.

Only one published study has examined biological markers in children at risk for panic disorder by virtue of panic disorder in their parents (55). Thirty-nine children, 7–17 years old, were examined for mitral valve prolapse by cardiac auscultation and echocardiogram, lactate levels after maximal exercise, 24-hour urinary catecholamine levels, and platelet monoamine oxidase (MAO) activity. Although a trend toward higher 24-hour catecholamine levels and greater MAO activity were found in the high-risk children than in normal control subjects, there were no statistically significant differences between children of patients with panic disorder and normal control subjects on any of the tests.

TREATMENT FOR PANIC ATTACKS: BEHAVIORAL AND PHARMACOLOGICAL APPROACHES

Behavioral and cognitive therapy as well as pharmacotherapy have been systematically tested in adults but not in children or adolescents with panic disorder. Clinical trials in adults have shown that exposure (56) and medications such as tricyclic antidepressants (57), fluoxetine (58), alprazolam (59), lorazepam (60), and clonazepam (61) are effective in reducing the symptoms of panic. The use of cognitive and behavioral treatment in children with anxiety, particularly fears and phobias, has been reported in open trials and clinical practice (62), but there are no controlled clinical trials of these

treatments with children. Pharmacological studies in children with anxiety disorders in general have been extremely limited and include neuroleptics, psychostimulants, antihistamines, and anxiety and antidepressant medications. The data so far are inclusive and limited. Therefore, there is no scientific basis yet to support the use of these medications in children with anxiety disorders, with the possible exceptions of tricyclic antidepressants for separation anxiety disorder and obsessive-compulsive disorder (63). Pharmacological treatments that are efficacious in adults with panic disorder have been used in clinical practice for children with panic (14, 20, 21), but clinical trials are absent.

IMPLICATIONS FOR FUTURE RESEARCH AND CASE FINDING

Our review suggests a number of potential directions for future research on panic attacks and/or panic disorder in children and adolescents. Information that is emerging from the studies of adults with panic disorder could fruitfully be extended. This could include studies of the natural history and clinical course of children whose panic disorder and symptoms were systematically diagnosed and assessed and who were followed longitudinally, family-genetic studies of children with panic to attempt to replicate the familial aggregation findings found in adults, studies of the biological markers of panic in children, and controlled clinical trials of behavioral and pharmacological approaches for the treatment of panic in children.

Thorough diagnostic evaluations using structured diagnostic interviews and *DSM-III-R* criteria could be conducted in children with panic disorder. These children could be followed longitudinally to determine the evolution of symptoms as well as the natural history and course of childhood-onset panic disorder. Do children with panic disorder continue to have panic when they reach adulthood?

Biological studies that have proved fruitful in adult patients with panic and that pose no psychological or physical threat to the child (examples include echocardiograms and determining catecholamine levels) could be conducted to determine the prevalence of mitral valve prolapse in children with panic disorder and in children with other anxiety disorders or with no anxiety disorders. Do children with panic have higher mean 24-hour catecholamine levels than children with other anxiety disorders or children with no anxiety disorders?

Finally, research methods and designs used to study behavior therapy and pharmacological therapy in adult patients with panic disorder could be applied to the study of children with panic disorder. It would be important to compare differences and similarities among children, adolescents, and adults with panic disorders to determine if and how age affects treatment response.

In terms of case finding, children with panic disorder, like adults with the disorder, probably are brought to emergency and medical clinics for physical symptoms

(i.e., hyperventilation, dizziness, palpitations), and their diagnosis may go unrecognized. Therefore, pediatric and neurology clinics and pediatric emergency rooms may be important areas for case finding. In addition, there is reasonable evidence that children of parents with panic and anxiety disorders are at greater risk for having panic, so some of the cases may be found in these families.

Our review suggests that panic disorder occurs in adolescents and, less frequently, in prepubertal children. The field is ripe for a host of studies developed in adults to be extended to children. These studies must, of course, take into account the special needs of and precautions for this younger age group.

Clinical Problem Solving and the Biopsychosocial Model

John Z. Sadler, M.D., and Yosaf F. Hulgus, Ph.D.

Engel's biopsychosocial model, while unifying the sciences relevant to medicine under general systems theory, is of limited utility in organizing bedside clinical problem solving. The authors consider this issue in light of the structure and goals of the clinical encounter. The biopsychosocial model is a model for organizing the sciences relevant to medicine; however, medical/psychiatric practice poses problems both within and outside the scientific realm. Since the biopsychosocial model cannot account for clinical problems to which the methods of science do not apply, the authors seek to facilitate biopsychosocial problem solving by proposing a clinical decision-making model that complements the biopsychosocial model. Their model directs the clinician's attention to three core aspects of the clinical encounter: problems of knowledge, ethics, and pragmatics. The authors reconsider Engel's case of Mr. Glover to demonstrate the anticipatory emphasis of the model. Other clinical examples are used to demonstrate the difficulties arising from mistaking one kind of aspect of medicine for another. When these three aspects of medicine are respected equally, a biopsychosocial practice is unavoidable.

(Am J Psychiatry 1992; 149:1315-1323)

The biopsychosocial model of medicine and psychiatry (1, 2) is an influential paradigm in psychiatry (3), family practice (4), and research (particularly psychiatric research) (5). It provides models for treatment by emphasizing the multidimensional nature of medical problems and demonstrating the functional interdependence of these multiple dimensions. Yet, to what degree does the biopsychosocial model actually shape clinical decisions? Concerns are frequently voiced about its lack of utility in everyday clinical decision making (6-9), its inability to differentiate important from unimportant clinical data (7, 8), and the tendency for it to be used in understanding clinical situations retrospectively rather than prospectively (7, 8). One empirical study (10) demonstrated that medical students prefer to use biomedical rather than biopsychosocial conceptions of illness, and another study (11) verified this trend among clinicians treating mood disorders. Psychiatrists are no exception to this tendency to have difficulty in using the biopsychosocial model. Paul Fink, in his response to an APA presidential address (6), noted that the everyday applicability of the model is a critical problem for psychiatry. Indeed, Fink raised the possibility of "biopsychosocial" being but an empty catchword with little methodological bite.

The biopsychosocial model was intended to preserve scientific rigor while attending to the whole person. The model is based on general systems theory, in which the sciences are organized around a systems hierarchy (2, 12). The systems hierarchy is organized around levels of organization, the lowest of which is subatomic particles, and there is a progression up through higher levels such as the molecule, cell, organ, person, couple, community, and biosphere. Each system level is interdependent with the others, and none has functional priority over the others, at least in theory. This model was and is much needed, given the reductionism of the biomedical model that characterizes much practice and research (1, 13). The systems hierarchy provides a means for conceptualizing the often-observed dependence among biological, psychological, and social levels of organization.

Why has the biopsychosocial model had limited success in changing physicians' behavior in actual clinical problem solving? That is, why are physicians not *practicing* biopsychosocial medicine? There is surely a multiplicity of reasons: physicians vary in their time constraints, in their interest in nontechnical (or nonprocedural) aspects of patient care, and in their sources of professional satisfaction. Many of these preferences may be incompatible with practicing truly biopsychosocial medicine. There are also conceptual reasons for the biopsychosocial model's limited assistance in clinical problem solving. This article focuses on those reasons.

Two key conceptual problems shape the difficulties in using the biopsychosocial model (i.e., practicing biopsychosocial decision making). The first has to do with the systems hierarchy itself. The systems hierarchy is

not hierarchical: it provides no functional priority of one level over another (14), at least as far as clinical problem solving goes. The clinician-user has no guided priorities to structure clinical decisions. Thus, the clinician has no method for determining which system level is most critical to the problem at hand. The second conceptual problem has to do with the way the biopsychosocial model is conceived as a medical model. We will show that it methodologically limits the scope of medical inquiry in ways that are antithetical to Engel's (and biopsychosocial practitioners') intent.

First, however, let us review Engel's conception of the biopsychosocial model. According to Engel, the model is a scientific one: "In any consideration of a scientific model for medicine that would qualify as a successor to the biomedical model, be it the biopsychosocial or any other, the fundamental issue is whether physicians can in their study and care of patients be scientists and work scientifically in the human domain" (15, p. 113). The admirable thrust of Engel's lifework has been to open up all areas of medical life to scientific inquiry. Engel endorses this definition of science from Charles Odegaard: "Science represents man's most persistent effort to extend and organize knowledge by reasoned efforts that ultimately depend on evidence that can be consensually validated" (15, p. 115). For Engel, then, a medical model should be scientific, and for it to be scientific, its knowledge claims must be supported by reasons and evidence that are open to consensual validation. However, is scientific inquiry relevant to all problems that arise in the clinical encounter? The answer is no, if one considers ethical and practical problems a part of medical/psychiatric practice. Indeed, the methods of science, we will show, are very well-suited to establishing knowledge about areas relevant to medicine but are methodologically ill-suited to other problems in clinical practice. As the examples below illustrate, many significant clinical problems in medicine defy resolution with the methods of science alone. In his later work, Engel himself increasingly views the biopsychosocial model as a model for the scientific *aspects* of medicine, rather than a general medical model (15). The bulk of this article demonstrates the importance of ethical and practical problems to biopsychosocial decision making and proposes a simple complement to the biopsychosocial model that provides a biopsychosocial problem-solving method.

THE STRUCTURE OF THE CLINICAL ENCOUNTER

Before going further, we need to define some fundamental concepts that are relevant to the tasks of any medical model. First, what is the context or situation in which the goals of medicine are realized? Fundamentally, these goals are realized in the clinical encounter—the clinical relationship between the physician and the patient. Medical research, public health, and so forth play supportive roles when the *practice* of medicine is considered.

The various sorts of events that transpire in a doctor-patient relationship are what we call the clinical content. Because the clinical encounter is conducted over time, the clinical content changes over time. Examples of clinical content could include taking a psychiatric history, performing a physical examination, performing a gastric lavage, discussing a treatment compliance problem with a cocaine addict, or making a psychotherapeutic interpretation. In the course of the clinical encounter, the clinician attends to some things and ignores others. The clinician's attention is selective, and the object of attention is thematic for that moment. The theme of the encounter is the clinical content that the physician selects at a particular point. A particular kind of clinical theme is the clinical problem (16). Clinical problems are nodal themes in the clinical encounter, since they often provoke changes in the clinician's inquiries or prompt the clinician to take therapeutic action. Examples of clinical problems could include determining the diagnosis of schizophrenia, evaluating the role of cholecystokinin in cholelithiasis, managing blood loss in a gunshot victim, improving a patient's compliance with an antihypertensive medication regimen, or deciding whether to fund treatment for the homeless mentally ill rather than prenatal care for the medically indigent. Clinical problems reflect the broad diversity of difficulties in rendering health care.

The clinical problem is the fundamental unit of decision making in the clinical encounter (16). Indeed, a focus on clinical problems (instead of disease entities) has already established itself in psychiatric record keeping (17–20). The idea that clinical problems are the fundamental unit of medical decision making is quite different from the usual idea that a diagnosis, disease, or illness is the fundamental unit. However, considering the actual decisions a clinician makes in everyday work will make this point obvious.

Consider this fictionalized example of a clinician's activities today. Perhaps he came into the office at 8:00 a.m. and found a statement from an insurance company that is supposed to be paying for his treatment of an adolescent with borderline personality disorder. The company says his treatment was unnecessary and it will not pay. Perhaps he had a 9:00 a.m. patient that he could not see until 9:40. Now the patient is very angry. He might wonder how to deal with the patient's anger. Or perhaps he consulted with the family of a patient in the intensive care unit whose intracranial hemorrhage has left her in a coma for 11 days. He might wonder when to begin discussing discontinuation of treatment with her family.

The point in these examples is that the clinician's decision-making process is not limited to diagnostic/treatment considerations at all; instead, it focuses on the everyday problems that clinical work presents. Moreover, clinical problems are not limited to explaining biological factors, understanding behaviors or meanings, or integrating these data. Nevertheless, these activities encompass the task of scientific medicine as

Engel conceives it. Our examples here and later illustrate that scientific understanding is only a part of the larger task of taking clinical action. A medical model that embraces only scientific understandings will not address important clinical problems.

How can we conceptualize a clinical method that will answer the complete range of clinical tasks? On the basis of Pellegrino's analysis of the clinical encounter (21-23), we propose three types of clinical content and, derivatively, three types of clinical problems. These three "faces" of medicine embrace a biopsychosocial approach and provide the means for addressing the special categories of clinical problems we have mentioned. The three faces or aspects are the epistemic aspect, the ethical aspect, and the pragmatic aspect.

The Three Faces of Medicine

Epistemic aspect. This aspect of medicine concerns much of the scientific or empirical basis of the clinical encounter. The epistemic aspect has to do with clinical knowing. When considering the contribution of basic and clinical science to clinical decision making, one is probably considering the epistemic aspect of medicine. For example, the epistemic aspects of medicine could include conceptualizing and testing a diagnostic classification system for psychiatric disorders, making a clinical diagnosis, choosing a treatment based on studies of clinical efficacy, or choosing the best approach in counseling a stubborn patient. The epistemic aspects pertain to understanding or explaining clinical events.

Ethical aspect. This aspect includes factors in the clinical encounter related to choosing preferable (in the evaluative sense) courses of action. Ethical aspects of medicine could include decisions about risk/benefit ratios for treatments, the justification for withholding important treatment information from a patient, or decisions about distributing scarce treatment resources, such as intensive care beds. The ethical aspects of medicine deal with values, and ethical problems have to do with 1) value conflicts between doctor, patient, and relevant others, such as nurses, families, and society, and 2) threats to valued things or values themselves, such as a diabetic patient's loss of a leg and subsequent loss of independence. The ethical aspect forces clinical decisions based not on science alone but on values as well (24). This is one reason why the biopsychosocial model, as currently formulated, is of limited assistance in dealing with this category of clinical problem: the biopsychosocial model is a narrowly defined medical model with science as its core method. How can a method for the attainment of knowledge resolve problems involving a clash of values?

Pragmatic aspect. This aspect pertains to translating clinical knowledge and ethical choice into effective therapeutic action. Pragmatics pertain to what is done or what action is taken. Pragmatics are necessarily intersubjective—relevant to actual dealings with people. The pragmatic aspects will often emphasize predicting clinical events. Examples could include modifying a

drug regimen according to anticipated drug interactions, anticipating potential problems with treatment compliance in a patient of a different ethnic background, modifying office management procedures, or meeting Medicare payment guidelines. A pragmatic problem could be not knowing what to do or how to do some relevant task. A pragmatic problem may involve not having sufficient supplies, materials, or assistance, i.e., not having drugs or equipment available. Pragmatic problems prevent effective therapeutic action. The science and art of prognosis is a clinical area in which pragmatics is made concrete. Pragmatic aspects of medicine require actions based on common-sense (or other utilitarian) criteria. Thus, medical scientific knowledge, or the pursuit of it, is only a requirement of, but not the same as, pragmatic *doing*.

Three aspects of one medicine. The three aspects of medicine can be considered explicitly or implicitly in any clinical situation. That is, a clinician can apply each of these aspects to a clinical theme in greater or lesser degrees. Significant overlap from epistemic to ethical to pragmatic aspects occurs. Consider this example from consultation-liaison psychiatry. The clinician is admitting a reluctant and delirious patient to the coronary care unit. The obvious pragmatic problem is considering what to do next if the patient refuses admission. Epistemic considerations could include choosing an interviewing approach that will enhance the patient's consent to admission. At the same time, an ethical consideration could be the status of the patient's competence to choose admission, with the attendant conflict of protecting or restricting the patient's freedom. Note that these three aspects are simultaneously present in the clinical encounter, yet they are distinguishable from one another. Each aspect illuminates the clinical goals by providing a relevant context for those goals.

It may be tempting to (mis)construe our intent as merely renaming the psychosocial aspects of medicine as the ethical and pragmatic aspects of medicine. This would miss a major point of this article. The psychosocial aspects of medicine as described by Engel have to do with the scientific conceptions of the nonbiological aspects of human life: those aspects of life that are studied by scientific disciplines such as psychology, sociology, and anthropology. The ethical and pragmatic aspects reflect a much broader context of study, one that may include these sciences but also include disciplines that are not scientific at all and are perhaps more properly considered humanities. For example, solving an ethical problem may require moral philosophy, while solving a pragmatic problem may require a business management technique. Most important, ethical problems in medicine require their own method for problem solving, that of resolving competing values. Pragmatic problems require their own method for problem solving, too; that is, common sense. (Ironically, systems theory has much to offer common sense!) Both ethics and pragmatics are readily distinguishable from the knowledge-acquiring methods of science.

Advantages of Considering the Three Faces

Precisely because both biomedicine and biopsychosocial medicine are properly scientific models for the scientific part of medicine, these models fall short in accounting for the complete clinical encounter by excluding pragmatic and ethical meaning and the taking of clinical action based on those meanings. Clinical problems in these models formally focus on epistemic problems exclusively: What is the diagnosis? What is the most effective treatment? What does this symptom mean? If students and residents are trained to make inquiries about only scientific facts concerning a patient (10, 25–29), then they will ignore the ethical and practical problems that so stubbornly impede the realization of therapeutic goals. The patient is dehumanized—is functionally an object for scientific study. These students mature into practitioners who resent and avoid the ethical and practical aspects that have always been part of medical practice. When only fact gathering is emphasized to students, ethical and pragmatic problems are made a troublesome, intrusive irritant in the practice of scientific medicine.

However, by formally considering the three aspects of medicine, the clinician cannot avoid practicing biopsychosocial medicine as it was ideally intended. When the clinician seriously considers and acts upon ethical and pragmatic clinical problems (as well as epistemic ones), the biopsychosocial approach cannot be avoided or ignored. How can one solve ethical problems without considering the values, wishes, ambivalences, and personal histories of the people involved? How can a clash of values be understood without making an empathic connection? How can one solve practical problems without considering the social systems that influence the patient or without considering the psychological and social sciences? Once the epistemic, pragmatic, and ethical dimensions of the clinical encounter are considered equally, the biopsychosocial perspective is unavoidable. In considering these three faces of medicine, the biopsychosocial approach is utilized by focusing reasoning and inquiry, without reviewing every science relevant to medicine. Indeed, what drives clinical decisions is not a structural hierarchy but the moral goals of the clinical encounter (8).

What do we mean by considering the three faces? We mean simply that every clinical problem has a theme that is reflected by the three faces, as in the example of the reluctant delirious patient. One or more themes may be explicit, others implicit. In our example, admitting a reluctant patient to the hospital is a pragmatic theme. However, when we ask ourselves how to solve this problem, the overlap with the epistemic and ethical themes can emerge. How should the patient be approached? Is the patient competent?

In order to realize therapeutic goals, the clinician's decision making must provide a way of planning for, or anticipating, future clinical problems. The biomedical model anticipates future clinical (epistemic) problems through its discipline of pathology, which predicts the

longitudinal course of diseases. The biopsychosocial model of Engel recommends a diversity-of-sciences approach but provides no guidelines for selecting the science that applies to a particular patient at a particular time (7). Moreover, the biopsychosocial model provides no formal method of anticipating the idiosyncratic problems that every individual patient presents; only the interdependence of the various system levels is emphasized. The three-aspect method proposed here acknowledges the importance of scientific explanation and prediction while also accounting for the individual, unique person.

RECONSIDERATION OF THE CASE OF MR. GLOVER

In Engel's classic article "The Clinical Application of the Biopsychosocial Model" (2), the case of Mr. Glover provides an example for the application of the biopsychosocial model. We will recast this familiar case to illustrate the three faces decision-making model as well as to highlight the differences between the biomedical model, the biopsychosocial model, and the supplemented biopsychosocial model we propose.

In the original case, Mr. Glover, a driven, overly responsible man, suffers his second myocardial infarction at work. Denying to himself the seriousness of his illness, he continues working until his boss notices his visible discomfort and convinces him to go to the hospital. There he relaxes until an inept intern repeatedly fails to obtain an arterial blood sample. Unnerved and in pain, Mr. Glover begins to doubt the competence of the hospital staff, and his chest pain increases again as his anxiety mounts. He loses consciousness as ventricular fibrillation ensues. The hospital staff jump to the conclusion that he was lucky to be in the hospital when this happened, or else he would be dead. The doctors fail to realize that events that occurred in the hospital may have contributed to Mr. Glover's cardiac arrest (8).

How does the biomedical clinician interpret this case? How does the biomedical clinician decide what data are clinically meaningful or important? The biomedical model would emphasize the importance of the empirical signs and symptoms of myocardial infarction and would bring to bear action that would address the acute course of this disease, including the increased risk of fatal cardiac arrhythmias. The biological aspects of the case would be seen as therapeutically and etiologically most important, with the psychosocial aspects relegated to the background if they are considered at all.

In contrast, the biopsychosocial clinician would emphasize the interdependency of biological and psychosocial contributions to Mr. Glover's illness. In retrospect, the anxiogenic effects of the failed attempts at obtaining an arterial blood sample would be considered important to the development of arrhythmias. This is an example of how the interpersonal system level would have a direct impact on the organ and cellular levels, and vice versa. Note that precisely *how* a particular case interpretation is developed is not clear with either model.

In the case of the biopsychosocial model, the clinician is left without guidance toward anticipating and effectively intervening at the appropriate system level. Moreover, as we will describe, certain aspects of clinical reality are deemphasized by both models.

For the recasting of Mr. Glover's case, let us put ourselves in the place of the clinician in the emergency room, where the actual first meeting with Mr. Glover would occur. The physician would have no information about Mr. Glover other than what he or she could obtain firsthand. This scenario will illustrate the application of the three faces of medicine under conditions that are more reflective of a real clinical encounter. This is important, because the test of a problem-solving model is its utility in the face of uncertainty.

Let's say that Dr. Smith is now meeting Mr. Glover to examine him in the emergency room.

Smith: Hello, I'm Dr. Smith. What seems to be the trouble?

Glover: Aw, I've been having some chest pain. I don't think it's a big deal, but my boss insisted that I come in.

Smith: You've had this sort of thing before?

Glover: Yeah, I had a heart attack 6 months ago.

Smith: You've broken out into a sweat and look pretty pale. Let me get you to lie down while I have the nurse hook up an ECG. Tell me more about your heart disease.

Glover: I had a heart attack 6 months ago; since then I've only needed to take nitroglycerin occasionally. You don't think this is another heart attack, do you?

Smith: That remains to be seen, but in the meantime, we ought to keep you comfortable. How much pain are you having?

Glover: It was hurting quite a bit at work, but it's a little better now.

Smith: Any other symptoms?

Glover: I had nausea at work and felt weak.

Smith: Where does it hurt?

Glover: Here (points to substernal region) and down this (left) arm.

Smith: Just like your heart attack before?

Glover: Pretty much.

Smith (examining Glover's chest): I think there's a good chance you're having another heart attack, so I want you to take it easy for now. There will be an intern coming in to draw some blood and finish your exam, and the nurse will give you some pain medication and some Valium.

The initial clinical priority in any first-time clinical encounter is making sense of the patient's clinical complaints. This is obvious and an example of an epistemic problem, namely, understanding Mr. Glover's medical problem. Dr. Smith accepts Mr. Glover's complaint of chest pain at face value and tries to characterize it as one of the many types of chest pain he has encountered in his training and experience. In this way, he may statistically specify and predict potential events of clinical significance. Thus, this aspect of his clinical inquiry resembles a natural scientific inquiry, explanation, and prediction (30, 31).

As Dr. Smith conducts his inquiry into the chest pain, he anticipates potential new clinical problems. This anticipation of future problems is the initial priority of the pragmatic face of medicine. The tentative diagnosis of

myocardial infarction foretells a range of dangerous clinical possibilities. Dr. Smith notes the incongruity between Mr. Glover's casual dismissal of his complaint as "some chest pain" and his observable diaphoresis and pallor. Dr. Smith wonders whether Mr. Glover is denying to himself the severity of his illness. Dr. Smith sees this as an important potential pragmatic problem; if Mr. Glover is seriously ill and denies it, he may refuse lifesaving treatments. Dr. Smith keeps in mind this hypothesis of Mr. Glover's denial for later interactions with Mr. Glover.

The ethical aspects of this encounter are more implicit. The ethical priority is to ask the question, What values are at stake when I take any clinical action? Dr. Smith works in a setting—the emergency room—where the ethics are significantly different from those of other outpatient or inpatient settings. For example, Dr. Smith feels less bound to provide careful disclosure for informed consent, because such disclosures interfere with undertaking effective and potentially lifesaving therapeutic action in the limited time available. Thus, Dr. Smith has in effect decided to override the ethical demand for complete disclosure at this time. However, if Mr. Glover contests this relative lack of disclosure, the ethical aspects of the case could emerge as an ethical problem that would demand attention from Dr. Smith. Dr. Smith, then, as a biopsychosocial clinician, should attend to Mr. Glover's wishes for more information.

Glover: Valium? What for?

Smith: To help you relax so your heart won't have to work so hard.

Glover: It's not going to knock me out is it? I want to know what's going on.

Smith: Let's see how you do with the pain medicine alone, but it's important that you relax. (Dr. Smith leaves the room, and nurse Brown attends to Mr. Glover.)

Glover (to nurse): You know, I really didn't want to come in here because of my work, but now I do feel a lot better. What is this pain medicine anyway?

Brown (smiling): Morphine; it should help you feel even better.

Glover: Seems like pretty strong stuff for chest pain.

Brown: We don't want people with heart attacks to hurt. (Nurse Brown attends to various technical procedures and leaves as intern enters.)

Dr. Smith's sensitivity to a potential ethical problem is borne out by Mr. Glover's behavioral response to the offering of analgesics and anxiolytics. Mr. Glover's concern about avoiding excessive sedation and maintaining control of himself suggests to Dr. Smith the potential for power struggles with the patient. Recognizing Mr. Glover's compulsive personality style, Dr. Smith compromises a pragmatic goal, control of anxiety, in order to obviate an ethical conflict, that is, handling Mr. Glover's implicit refusal of diazepam. At the same time, Dr. Smith brings to bear a rudimentary knowledge (epistemic aspect) of the compulsive personality in shaping his choice to forgo the diazepam.

Dr. Smith, as a preceptor to his intern, now turns his attention to the encounter with Dr. Young and Mr.

Glover. Ever vigilant, he pragmatically considers what potential problems could emerge from this interaction as he moves to the next patient in the next room. He wonders whether Dr. Young's own anxiety about doctoring will somehow compound Mr. Glover's anxiety and makes a mental note to check in on them shortly.

Young: Hi, Mr. Glover. I'm Dr. Young, the intern working with Dr. Smith. I need to go over some of the information again that you discussed with Dr. Smith and do a more complete physical.

Glover (sighing): Okay. (Dr. Young takes the history and examines Mr. Glover.)

Young: Mr. Glover, I need to take an arterial blood sample from you to determine if your blood has enough oxygen. You can expect the stick to hurt some.

Glover (tensing up): Can I look?

Young: If you want. (Dr. Young attempts to draw the arterial blood but has difficulties. After Dr. Young has made several unsuccessful attempts, Dr. Smith returns, as he had planned.)

Smith: How's it going?

Young (nervously): Fine.

Glover (anxious and in pain): Can't this guy just get the blood?

Smith (diplomatically, to Dr. Young): Let's get Ms. Brown to hold his wrist while we go over another case. Mr. Glover, I don't think the arterial blood sample is essential at this time. Let's hold off on it until you're more comfortable. How's your chest pain?

Glover (relieved): Better, thanks.

Smith (looking at the ECG monitor): You got pretty excited with that stick, but you're already settling down.

Glover: You'll be back soon?

Smith: Sure. In the meantime, Ms. Brown will be with you. (Mr. Glover is taken to the coronary care unit without complications.)

When Dr. Smith reenters the room, witnessing Mr. Glover's clenched teeth and grimace, he immediately concludes that things are not going well at all, despite Dr. Young's reassurances. Effective action is needed, and Dr. Smith has a number of important pragmatic factors to consider before acting. Is Mr. Glover dyspneic enough to warrant the arterial blood gas procedure? Is the need for the procedure more important than keeping Mr. Glover calm and collected? Is it ethical to allow Dr. Young, a trainee, to continue his painful attempts to draw arterial blood when these very attempts may present some degree of risk to Mr. Glover (i.e., precipitate a cardiac arrhythmia through increased sympathetic tone)? In his deliberation, Dr. Smith keeps in mind his goal of getting Mr. Glover safely to the intensive care unit. Dr. Smith's pragmatic consideration of these ethical and epistemic factors prompts his decision to withhold further attempts at the arterial blood gas procedure, and indeed he successfully transfers Mr. Glover to the intensive care unit.

Note that in this example, the three faces (epistemic, ethical, pragmatic) are interdependent. Dr. Smith's choice to withhold diazepam (a pragmatic move) is dependent on his knowledge (epistemic aspect) of the pathophysiology of myocardial infarction, the relation-

ship of anxiety to arrhythmia, and so on. Dr. Smith's withholding of diazepam is also dependent on his view of the ethics of paternalism, that is, how he views the conflict between a patient's refusal of treatment and the need for urgent and beneficent action. Dr. Smith's priorities are tripartite: 1) (epistemic aspect) what is the problem? 2) (pragmatic aspect) what actions need to be taken and what will be their consequences? 3) (ethical aspect) what value implications do my actions have? Precisely because he moves comfortably from clinical knowledge to clinical ethics to clinical pragmatics and back again, Dr. Smith is a truly biopsychosocial clinician. Working through the three faces provided him a problem-solving map for the uncertainties of on-your-feet practice.

THE PROBLEM OF CROSSED-ASPECT DECISION MAKING

Earlier in this article we discussed briefly the training of medical students—a process dominated by the lesson that medical science is the primary discipline relevant to the practice of medicine. These students may develop into practitioners whose expectation is that all clinical problems can be solved with the well-honed tools of the natural scientific inquiry. Indeed, the overwhelming majority of material in medical school curricula is basic and clinical science. For these students (and many practitioners), there is only one face of medicine: the epistemic aspect. The most obvious difficulty with single-aspect decision making is the one that inspired Engel's "biopsychosocial" response: attending to a narrowly defined science in medicine dismisses the broad range of human experience and dehumanizes patients. We now illustrate why the single-aspect approach to clinical decision making may often be fruitless in dealing with ethical and pragmatic problems and, in some cases, may be even dangerous to patients.

We use the term "crossed-aspect" decision making to describe the situation in which a clinical problem in one face of medicine is confused with another. The confusion or misidentification can lead to great difficulty in solving a clinical problem. This confusion can be avoided simply by reconsidering the clinical problem in light of all three faces or aspects.

Examples of Crossed-Aspect Decision Making

Applying an epistemic solution to an ethical problem. A colleague discussed with one of us an ethical problem that occurred in the context of the psychiatric emergency room. He had a patient, brought in by police, who was refusing to be meaningfully interviewed. The patient had a history of violent psychotic illness, so an evaluation would be essential if there was to be any possibility of his release into the community. Our colleague's problem was whether it was ethical to tell the patient, "You should talk to me, because if you don't, I have no choice but to commit you to the hospital."

Intrigued, we pursued his thinking about this problem. His solution was to survey the emergency room psychiatrists, asking them how they handled this situation. Our colleague was quite reluctant to consider what values were at stake. Instead, he thought that if the majority of the emergency room psychiatrists did it one way, that must be the right way. In effect, our colleague was applying an epistemic solution to a correctly identified ethical problem. What is disturbing, even dangerous, is his thinking that scientific data gathering, which indicated consensual agreement only, would be sufficient to suggest right (ethical) action. Of course, in some cases it could dictate a right action or, more likely, reveal some way of avoiding or circumventing the ethical problem. Nevertheless, what was needed to answer the ethical problem was a qualitative inquiry into the competing values at stake (32). The idea that consensual agreement about practices is adequate for making ethical choices can be dangerous. In the extreme it can result, as in Nazi Germany, in consensually agreed-upon atrocities (33). Inquiries that give equal respect to the three faces moderate the extremes of any single mode of decision making.

Mistaking a pragmatic problem for an ethical one. An internist, Dr. A, consulted one of us for an "ethical" problem he had with a critically ill, elderly patient. The patient, Mr. Z, had experienced cardiac arrest, had an anoxic cerebral injury, and was diagnosed as being in a persistent vegetative state. He had a living will and had told his internist and family members that if he became a "vegetable," he would not want to be kept alive artificially. The internist had planned to withdraw life-sustaining treatments, but he had been threatened with a lawsuit by Mr. A's estranged daughter. The daughter wished "everything be done" to keep Mr. Z alive, despite her knowledge that her father preferred otherwise. Dr. A was now hesitant to discontinue treatment. Upon further questioning, Dr. A outlined his rationale for the ethical discontinuation of Mr. Z's treatment. It became clear to him, and to us, that his best ethical judgment—to discontinue treatment—was reasonable; thus, problem-solving efforts should be focused instead on the practical (pragmatic) problem posed by the daughter: litigation. The case was resolved by bringing in the hospital attorney to discuss the case with the daughter. Treatment was discontinued, Mr. Z died peacefully, and no litigation ensued.

Seeking more "facts" to solve ethical or pragmatic problems. This kind of crossed-aspect error demonstrates persistence in thinking about clinical problems as exclusively epistemic-aspect scientific problems. In the context of an ethics conference, a case was presented in which a psychiatrist (Dr. B) had to choose whether or not to inform the fiancée (Ms. X) of the patient (Mr. Y) of his HIV-positive clinical status. To complicate matters, Ms. X was also a patient of Dr. B. The identified problem was the ethics of breaching confidence about Mr. Y's HIV status in order to provide possibly lifesaving information to his fiancée. The questions raised by several residents betrayed discomfort

about grappling with the ethics or values in conflict. They asked questions about the clinical status of Mr. Y and details of the couple's engagement: What signs or symptoms of AIDS or AIDS-related complex did Mr. Y have? How long had Mr. Y been under the physician's care? What was the patient's psychiatric diagnosis? How long had the patient been engaged to Ms. X? Did Mr. Y otherwise have an honest and open relationship with Ms. X? Under what circumstances did Dr. B discover Mr. Y's HIV status?

After this information had been disclosed, the residents came to realize that the new information shed very little light on the problem at hand. A discussion of the conflicting duties, including ethical obligations as well as legal (pragmatic) ones, resulted in a near-consensus on the decision that Dr. B should try first to persuade Mr. Y to tell his fiancée himself, and failing that, Dr. B should inform Ms. X. This example shows that scientifically driven fact gathering can detour decision making that is more efficiently handled within the ethical or pragmatic mode of reasoning. This is not to dismiss the value of scientific inquiry or the acquisition of relevant facts regarding ethical problems. Rather, this example suggests that adding the ethical and pragmatic modes of thinking can be fruitful and efficient. Indeed, crossed-aspect decision making emphasizes the interdependent nature of the three aspects; for example, an inquiry into the values at stake can help in determining the relevant facts, and the relevant facts of the case can shed light on the values at stake.

There are many other possible examples of crossed-aspect failures in clinical decision making. It would be misleading, however, to suggest that a problem in a single face or aspect requires a solution in that aspect—for example, that an ethical problem requires a value-based solution. Frequently, a clinical problem in one aspect can be resolved within another aspect. Reconsider the case of Mr. Y. If Dr. B had been able to persuade Mr. Y to tell his fiancée of his HIV status, Dr. B would have used a pragmatic solution to obviate a more ethically profound decision: to breach or not to breach confidentiality.

DISCUSSION

The biopsychosocial model reflects a particular theory as well as an intended ideal. It is the ideal or spirit that has influenced us the most. The biopsychosocial model, for us, symbolizes humane, empathic, yet rigorous medical care. It is in this spirit that we make the distinction between the importance of the biopsychosocial model and having a concrete method for making humane, empathic, and rigorous clinical decisions.

The clinical method introduced here is intended to render the biopsychosocial model more useful in clinical decision making. As we have argued, however, clinical decision making requires a disciplinary scope much broader than science alone can offer. The three faces or aspects can provide a conceptual shorthand for system-

atically examining the breadth of clinical decision making. Figure 1 shows the conceptual scope of the biopsychosocial model and that of the three faces decision-making model described here. It underscores the fact that the complementarity of the three faces model is not simply a matter of semantics. Making biopsychosocial decisions involves ways of reasoning besides scientific thinking. Figure 1 may lead the reader to think that we are adding to the complexity of the biopsychosocial model. In a sense we are, and in a sense we are not. Complexity is suggested by the set of extra formal disciplines that are relevant to biopsychosocial medicine. However, in another way we are not adding complexity. We are not advocating a review of every science in figure 1 before one makes a clinical decision. Indeed, this would counter the demands of the pragmatic face of medicine. With the systems hierarchy, the sciences relevant to psychiatry and medicine are a long list indeed. Should we review each of them before making a clinical decision? With the three aspects described here, clinical problems and decisions can be framed in three interrelated areas without going over each relevant science.

Engel himself recognized the limitation of the biopsychosocial model in problem solving and reconceptualized it in his later work (15) as a model for the science of medicine. To use our language, it is a model for the epistemic aspect of medicine. As such it is an attempt to integrate the pluralism of sciences within medicine. We consider the systems hierarchy essential to research in

psychiatry and medicine, as a theoretical structure for interlevel research problems.

However, the diversity of sciences that embrace the epistemic aspect of medicine may not be the place to look for integration of patient care. It may be through pragmatic and ethical considerations that the wholeness and integrity of the patient can be preserved (34). After all, it is the patient's complaint or need that shapes the inquiries and actions in medicine. Science cannot address patients' needs directly; rather, pragmatic and ethical considerations are required in order to render treatment whole. Patients' practical and moral imperatives direct every therapeutic inquiry and action.

The basic clinical method offered here emphasizes the equivalent importance of epistemic, pragmatic, and ethical considerations in everyday clinical decision making. Further work is needed to describe how the clinician recognizes or distinguishes epistemic, pragmatic, and ethical problems in the clinical encounter. Furthermore, once a problem in a given aspect is recognized, a method is needed for selecting relevant information that contributes to solving the clinical problem (31, 34).

Clinical decision analysis has directed research attention toward clinical decision making and problem solving at least partly to enhance the teaching of clinical skills. However, the majority of work in decision analysis has focused on the problems of diagnosis and treatment (35) (i.e., epistemic aspects), while the incorporation of ethical (36) and practical concerns into these analytic procedures is rare. It seems unlikely that decision analysis will model human clinical decision making accurately without attending to clinical problems *per se* as well as the ethical and pragmatic aspects of medicine.

Research in education has demonstrated the disparity between so-called cognitive knowledge and clinical knowledge (37–40). This disparity is reflected in the three faces of medicine. Cognitive knowledge has to do with what we call the epistemic aspect of medicine, while clinical knowledge would reflect equally the epistemic, ethical, and pragmatic aspects of medicine. Even when we try to define away all but the epistemic aspects of medicine, ethics (36) and pragmatics stubbornly sneak into the problems that confront us. Forrow et al. (41) described the improvement of clinical care that clinical ethics has fostered and the new questions for research that clinical ethics has posed. What new questions does clinical pragmatics pose?

Clinical pragmatics raises questions having to do with taking effective therapeutic action. Some examples could include the following: How do we fund health care for the indigent? What kind of office management facilitates efficient delivery of care? How does a clinician effectively manage the medically ill patient with a personality disorder? What is the best triage system for an emergency room? How do we improve compliance with complicated drug regimens? The disciplines that would deal with these questions would be diverse indeed—biology, psychology, sociology, systems theory, economics, informatics, philosophy, business manage-

ment, and so on. Many of them are not science at all, at least in the formal sense. Many clinicians would claim that these questions have little to do with medicine (42) and certainly not with medical education. Can we afford to not study and teach about the ethical and practical aspects of medicine? Can we practice effective medicine without these considerations?

Melancholic/Endogenous Depression and Response to Somatic Treatment and Placebo

Eric D. Peselow, M.D., Michael P. Sanfilipo, M.S.,
Constance Difiglia, M.D., and Ronald R. Fieve, M.D.

Objective: The authors' goals were to examine the effects of somatic treatment and placebo in patients with and without endogenous/melancholic depression. **Method:** Before entry into one of four trials of antidepressant drugs versus placebo, 231 patients were assessed as to whether they met Research Diagnostic Criteria for definite endogenous depression and/or DSM-III criteria for major depressive episode with melancholia. These patients were prospectively assessed for subsequent response to antidepressant treatment or placebo. Previous studies of the effect of endogenous/melancholic depression on treatment response were also reviewed. **Results:** Of the 76 patients with DSM-III melancholia given active medication, 41 (54%) had a complete or partial response, but only 10 (23%) of the 44 patients with melancholia given placebo had a complete or partial response. Of the 76 depressed patients without melancholia given active medication, 46 (61%) had a complete or partial response, and 15 (43%) of the 35 depressed patients without melancholia given placebo had a complete or partial response. Moderately depressed patients with DSM-III melancholia had a significantly better response to active medication than did severely depressed patients with melancholia and showed the greatest difference between response to active medication and response to placebo. The results of the review of previous studies of the effect of endogenous/melancholic depression on treatment response were mixed. **Conclusions:** Depressed patients with melancholia were not particularly different from depressed patients without melancholia in their responses to antidepressant medication but did differ from patients without melancholia in their responses to active medication versus placebo, particularly if their depression was moderate and not severe. This suggests that patients with DSM-III melancholia may be unresponsive to nonsomatic treatments.

(Am J Psychiatry 1992; 149:1324-1334)

The melancholic and endogenous distinctions for describing depressive illness have been prominent for approximately 60 years (1, 2). It has been presumed that a diagnosis of melancholia or endogenous depression implies a biological rather than an environmental etiology and is usually present in individuals who have little or no maladaptive personality traits. The Research

Diagnostic Criteria (RDC) of Spitzer et al. (3) and APA's DSM-III criteria have assumed a particular pattern of symptoms for endogenous depression or melancholia, respectively, whereby the diagnosis is made according to a fairly similar set of symptom criteria. DSM-III-R includes six symptom criteria for melancholia originally listed in both RDC and DSM-III and also includes three historically based nonsymptom criteria (appendix 1).

Of the three historical criteria, the one that perhaps is most interesting and that we will concern ourselves with here is the inclusion of a "previous good response to specific and adequate somatic therapy." Despite the

common belief that "melancholics are particularly responsive to somatic treatment" (*DSM-III-R*), there is no research confirming this notion (4). It must be pointed out that many of the studies investigating this question have not examined the prognostic validity of the melancholic and/or endogenous depressive subtypes in relation to a placebo control group.

The main purpose of this paper was to examine prospectively the effects of antidepressants on depressed patients with and without melancholia and/or endogenous depression who participated in one of four antidepressant drug trials. This enabled us to assess whether the presence or absence of melancholic features had a role in response to antidepressant or placebo treatment. We also reviewed the literature examining the effect of endogenous/melancholic depression on treatment response.

METHOD

From June 1984 to June 1988, our group conducted four 6-week antidepressant drug trials: 1) fluoxetine hydrochloride (20–60 mg/day) versus placebo, 2) clovoxamine hydrochloride (100–350 mg/day) versus imipramine hydrochloride (70–245 mg/day) versus placebo, 3) fluoxetine hydrochloride (5–40 mg/day) versus placebo, and 4) paroxetine hydrochloride (10–50 mg/day) versus imipramine hydrochloride (65–275 mg/day) versus placebo. Overall, a total of 313 patients gave voluntary informed consent to participate in one of these four trials. Although there was some variation in the entry criteria for each study, all patients who were involved in these trials had a minimum initial score of 16 on the Hamilton Rating Scale for Depression (5).

At entry into each of these studies, patients were given the Hamilton Rating Scale for Depression (5), the self-rating Beck Depression Inventory (6), the Clinical Global Impression (CGI), the 3-point Raskin Depression Scale (6), and an endogenous depression scale abstracted from the Schedule for Affective Disorders and Schizophrenia—Change Version (7). As a result, we were able to assess whether a depressed outpatient met RDC for *definite* endogenous depression (3). Since the *DSM-III* symptom criteria for major depressive episode with melancholia are all included in the RDC for endogenous depression, we were also able to determine whether a patient met *DSM-III* criteria for melancholia. (As shown in appendix 1, the major difference between the RDC and the *DSM-III* criteria is that anhedonia and lack of reactivity to pleasurable stimuli are required for *DSM-III* melancholia but not for RDC endogenous depression.)

If a patient in any of the four studies met *DSM-III* criteria for major depressive episode and had a minimum score of 16 on the Hamilton Rating Scale for Depression, he or she was placed into a single-blind placebo phase for a mean of 7 days (range=5–10 days). Following the single-blind placebo period, patients were reassessed with the Hamilton Rating Scale for Depression, the Beck Depression Inventory, the CGI, and

the Raskin Depression Scale. If a patient's Hamilton score remained above 16 and did not drop more than 20% below the initial value before the single-blind placebo period, the patient was entered into one of the four 6-week double-blind trials of active medication versus placebo. Patients who entered the double-blind phase of these trials were seen and rated weekly with the same scales. At the end of 6 weeks (or 4–5 weeks if that was the endpoint of the study), a determination of response to treatment was made.

Since there is evidence in the literature that fluoxetine (8), clovoxamine (9), and paroxetine (10) have antidepressant efficacy, we combined patients who received these drugs and those who received imipramine into a single antidepressant drug group for the purposes of the data analysis. The placebo group was a combination of the placebo groups from the four individual studies. In addition, we collected data on patients who responded during the 5–10-day single-blind placebo period and compared them with patients who did not respond during this phase.

We decided that a minimum of 4 weeks in the double-blind phase was a sufficient amount of time to determine an adequate response to placebo or active medication. Of the 313 patients who agreed to participate in one of the four studies, 278 entered the double-blind phase. Of the 278, we obtained data on 231 patients, 191 of whom were treated for a full 6 weeks. Using the RDC for *definite* endogenous depression and the *DSM-III* criteria for major depressive episode with melancholia, we examined whether the presence of endogenous/melancholic depression was associated with antidepressant or placebo response.

RESULTS

Table 1 shows the response to 1 week of placebo administration of the patients with and without endogenous and/or melancholic depression who went on to the

^aRDC for endogenous depression, *DSM-III* criteria for major depressive episode with melancholia.

double-blind phase of the studies. Patients were categorized into four groups according to the presence or absence of RDC endogenous depression and *DSM-III* melancholia. After the 5–10-day single-blind placebo phase, 27 patients exhibited a 50% or greater reduction in their mean Hamilton and Beck scores from the initial screening value. These patients were considered placebo responders. Placebo responders were more likely not to meet both RDC for definite endogenous depression and *DSM-III* criteria for melancholia than were the placebo nonresponders (table 1).

The 231 single-blind placebo nonresponders were given active medication or placebo for at least 4 weeks (191 were treated for a full 6 weeks). Table 2 lists the initial mean Hamilton, Beck, CGI, and Raskin scores of the patients who did or did not meet the criteria for endogenous/melancholic depression. Differences among these groups with respect to initial (baseline) depression scores were examined with two simple one-way analysis of variance (ANOVA) models using scores from the depression scales as the dependent measures. Results of the ANOVA for the Hamilton scale were significant (table 2), and Student-Newman-Keuls post hoc tests revealed that individuals who met both RDC for endogenous depression and *DSM-III* criteria for melancholic depression had significantly higher Hamilton scores than patients in the other three groups. Results of the ANOVA for the Beck scale were also significant (table 2); however, the only significant difference was between patients who had both RDC endogenous depression and *DSM-III* melancholia and those who had neither.

A 4x2 (depression group by treatment group) analysis of covariance (ANCOVA) design with baseline depression score as the covariate was used to examine differences in posttreatment (endpoint) depression score. In considering both RDC and *DSM-III* criteria, in all ANCOVA models, the effect of baseline depression score was significant (p<0.001). For the ANCOVA model on the Hamilton scale, the main effects for depression group (F=3.74, df=3, 222, p=0.012) and for treatment group (F=12.83, df=1, 222, p<0.0001) were significant, but the depression-group-by-treatment-group interaction only approached significance (F=2.26, df=3, 222, p=0.08). For the ANCOVA model on the Beck scale, the main effect for treatment group was significant (F=14.18, df=3, 222, p<0.0001), but the main effect for depression group was not. The depression-group-by-treatment-group interaction was nearly significant (F=2.60, df=3, 222, p=0.053). The adjusted endpoint depression mean scores for the Hamilton and Beck scales are given in table 3.

TABLE 4. Response to Active Medication or Placebo of Depressed Patients With Different Degrees of Depressive Symptoms Who Did or Did Not Meet *DSM-III* Criteria for Major Depressive Episode With Melancholia

Response	Patients Who Met Criteria						Patients Who Did Not Meet Criteria					
	Active Medication			Placebo			Active Medication			Placebo		
	Total	N	%	Total	N	%	Total	N	%	Total	N	%
Patients with moderate depressive symptoms ^a	34			20			61			25		
Complete response		13	38.2		1	5.0		14	23.0		3	12.0
Partial response		12	35.3		5	25.0		23	37.7		9	36.0
No response		9	26.5		14	70.0		24	39.3		13	52.0
Patients with marked to severe depressive symptoms ^b	42			24			15			10		
Complete response		6	14.3		1	4.2		3	20.0		1	10.0
Partial response		10	23.8		5	12.5		6	40.0		2	20.0
No response		26	61.9		20	83.3		6	40.0		7	70.0
All patients ^c	76			44			76			35		
Complete response		19	25.0		2	4.6		17	22.4		4	11.4
Partial response		22	28.9		8	18.2		29	38.2		11	31.4
No response		35	46.1		34	77.3		30	39.5		20	57.1

^aSignificantly higher rates of complete or partial response in the patients who met criteria and were given active medication than in those who met criteria and were given placebo ($\chi^2=11.39$, $df=2$, $p=0.003$) and those who met criteria and were given active medication but started with marked to severe levels of depression ($\chi^2=10.29$, $df=2$, $p=0.006$).

^bNonsignificantly higher rates of complete or partial response in the patients who met criteria and were given active medication than in patients who met criteria and were given placebo ($\chi^2=3.48$, $df=2$, $p=0.18$).

^cSignificantly higher rates of complete or partial response in the patients who met criteria and were given active medication than in those who met criteria and were given placebo ($\chi^2=12.68$, $df=2$, $p=0.002$); nonsignificantly higher rates of complete or partial response in patients who did not meet criteria and were given active medication than in those who did not meet criteria and were given placebo ($\chi^2=3.48$, $df=2$, $p=0.18$).

These data were reanalyzed including only patients who met or did not meet *DSM-III* criteria for melancholia (without consideration of those who met RDC for endogenous depression) for four reasons. First, *DSM-III* criteria are used more universally than the RDC. Second, there was little difference in the absolute baseline and adjusted endpoint depression scores between individuals who had only *DSM-III* melancholia and those who had only RDC endogenous depression. Third, a slightly larger group difference between active medication and placebo was observed for individuals who had only *DSM-III* melancholia than in those who had only RDC endogenous depression. Fourth, collapsing these two groups provided greater statistical power to detect an apparent interaction effect.

The adjusted endpoint mean Hamilton and Beck scores of patients given antidepressant treatment or placebo who did or did not meet *DSM-III* criteria for melancholia are given in table 3. For endpoint Hamilton scores with baseline Hamilton scores as the covariate, the 2×2 (*DSM-III* group by treatment group) ANCOVA found that the *DSM-III* group main effect ($F=8.06$, $df=1$, 226, $p<0.005$), the treatment group main effect ($F=26.82$, $df=1$, 226, $p<0.0001$), and the *DSM-III*-group-by-treatment-group interaction ($F=4.05$, $df=1$, 226, $p=0.045$) were all significant. For endpoint Beck scores with baseline Beck scores as the covariate, the 2×2 (*DSM-III* group by treatment group) ANCOVA found that the treatment group main effect ($F=27.57$, $df=1$, 226, $p<0.0001$) and the *DSM-III*-group-by-treatment-group interaction ($F=4.81$, $df=1$, 226, $p=0.029$) were significant but the *DSM-III* group main effect was not. The formal use of simple main effects for interpretation of

the two significant ANCOVA interactions was not necessary (both factors had only two levels); each revealed that the difference between response to active medication and response to placebo was significant in patients with *DSM-III* melancholia but not in patients without melancholia.

Since individuals who received active medication still had high levels of depression at the endpoint of the study, stringent criteria were used to categorize the patients' response or nonresponse to active medication or placebo. A complete response was defined as having a 50% or greater mean reduction in Hamilton and Beck scores and an absolute endpoint score of 6 or less on the Hamilton scale. A partial response was defined as having just a 50% or greater mean reduction in Hamilton and Beck scores. Failure to meet either set of criteria was defined as nonresponse. Using these categories and the presence or absence of *DSM-III* melancholia, we performed a chi-square analysis on the relative rates of response to active medication and placebo. The results indicated that the 76 patients with *DSM-III* melancholia given active medication had a significantly higher rate of complete or partial response than did the 44 patients with *DSM-III* melancholia given placebo but that the 76 patients without *DSM-III* melancholia given active medication did not have a significantly different rate of complete or partial response than did the 35 patients without *DSM-III* melancholia given placebo (table 4).

The patients given the drugs approved by the Food and Drug Administration (FDA) (imipramine and fluoxetine) showed the same differential response to active medication and placebo when considered individu-

ally. That is, patients with *DSM-III* melancholia who were given imipramine had a complete or partial response rate of 60.9%, but patients with melancholia who were given placebo had a complete or partial response rate of only 22.7% ($\chi^2=7.57$, $df=1$, $p=0.005$); patients without melancholia who were given imipramine had a complete or partial response rate of 73.7%, and patients without melancholia who were given placebo had a complete or partial response rate of 44.9% ($\chi^2=3.34$, $df=1$, $p=0.09$). For fluoxetine, the active medication and placebo response rates for patients with melancholia were 55.6% and 22.7% ($\chi^2=7.76$, $df=1$, $p=0.006$), respectively, but the active medication and placebo response rates for patients without melancholia were 53.3% and 44.9% ($\chi^2=0.44$, $df=1$, $p=0.50$), respectively. The drugs not approved by the FDA (clovoxamine and paroxetine) showed an overall difference between drug and placebo. This is, depressed patients with and without melancholia who were given these drugs or placebo had statistically different response rates to active medication and placebo (54.5% versus 31.6%) ($\chi^2=6.75$, $df=2$, $p<0.04$). However, when the patients were divided into those with and those without melancholia, the number of subjects in each group was too small to obtain statistically significant results.

We subdivided all of the patients with and without *DSM-III* melancholia by whether they started with moderate (CGI score of 4) or marked to severe (CGI score of 5 or 6) levels of depression and examined the response rates to active medication and placebo. The results of this analysis are given in table 4. The best response to active medication was shown by the patients with melancholia who started with moderate depression: 74% of these patients had a complete or partial response to active medication, compared with 38% of the patients with melancholia given active medication who started with marked to severe depression and 30% of the patients with melancholia given placebo who started with moderate depression. The response rate to active medication of the patients with melancholia who started with marked to severe depression was not significantly higher than the response rate to placebo of patients with melancholia who started with marked to severe depression.

It should be noted that the differential between response to active medication and response to placebo for the moderately and severely depressed groups was similar for patients who underwent 6 weeks of treatment ($N=191$) and those who were treated for only 4–5 weeks ($N=40$). Of the 37 severely depressed patients with melancholia who underwent a full 6 weeks of treatment with active medication, 16 (43.2%) had a complete or partial response; of the 16 severely depressed patients with melancholia who underwent a full 6 weeks of treatment with placebo, four (25%) had a complete or partial response ($\chi^2=0.90$, $df=1$, $p=0.34$), which argues against the idea that nonresponse in this group of severely depressed patients was due merely to an insufficient amount of time for drug efficacy (11, 12).

DISCUSSION

Previous studies examining the effect of endogenous/melancholic depression on treatment response (13–38), summarized in tables 5–8, have had mixed results. It must be pointed out that only a few of the studies were specifically designed to assess the prognostic validity of melancholic/endogenous subtyping. The majority of these studies either assessed a variety of factors regarding the prognostic validity of drug response (one of which was the presence or absence of endogenous depression) or were placebo-controlled studies assessing whether a particular treatment was efficacious and merely noted the presence or absence of endogenous/melancholic features for each patient in the trial.

The majority of the studies that examined somatic treatments in patients with or without endogenous/melancholic depression with no placebo control group (13–18) or without comment on a placebo control group (19–23) suggested that the presence of endogenous/melancholic depression did not predict a good response to somatic treatment (table 5). If there had been no placebo control groups for the four studies reported here, we would have made the same conclusion, because the results showed that there was no difference between the *DSM-III* groups with respect to drug response. It is interesting to note that Davidson et al. (21–23) found that when RDC for endogenous depression were applied, 70% of the patients with nonendogenous depression, compared with 45% of the patients with endogenous depression, responded to isocarboxazid according to scores on the Hamilton scale. When *DSM-III* criteria for melancholia were applied, they found that 65% of the patients without melancholia responded to isocarboxazid compared with 43% of those with melancholia.

Although the presence of endogenous/melancholic symptoms is thought to predict a poor response to nonbiological therapies, the three studies on this topic (24–26) were inconclusive (table 6). Prusoff et al. (24) found that patients with endogenous symptoms had a poor response to interpersonal psychotherapy, unlike patients without endogenous symptoms. Two other studies of cognitive therapy compared with pharmacotherapy (25, 26), however, found that the presence or absence of endogenous depression did not predict response to cognitive therapy, pharmacotherapy, or a combination of these two treatments.

Studies that evaluated patients with and without endogenous/melancholic depression given either placebo (27, 28) or no treatment (29) have yielded mixed results (table 7). Rabkin et al. (27) found that 36% of the patients who initially responded to placebo and subsequently relapsed had a diagnosis of endogenous depression, compared with 24% of those who remained well. Fairchild et al. (28) found that only one of 21 patients who responded to placebo after 1 or 5 weeks had RDC-diagnosed endogenous depression but that 17 of 34 patients who did not respond to placebo had endogenous depression. This study had a flaw in that

TABLE 5. Studies That Evaluated Medication and/or Somatic Treatments Without Placebo Group or Without Comment on a Placebo Group in Depressed Patients With or Without Endogenous/Melancholic Depression

Study	Year	Design	Patients	Results and Comments
Coryell et al. (13)	1980	Evaluated predictors of response in depressed outpatients treated with amitriptyline or nortriptyline treated for 6 weeks	44 patients	Presence or absence of specific endogenous or nonendogenous symptoms did not predict response to either drug
Kupfer and Spiker (14)	1981	Evaluated clinical predictors in inpatients treated with amitriptyline for at least 2 weeks	Of 76 patients, 54 had endogenous symptoms	Presence of endogenous depression did not predict good response
Razani et al. (15)	1983	Evaluated efficacy of amitriptyline, tranylcypromine, and amitriptyline plus tranylcypromine in treating major depression	Of 60 patients randomized to three groups, 22 met <i>DSM-III</i> criteria for melancholia	Presence or absence of melancholia did not predict response to any treatment
Coryell and Zimmerman (16)	1984	Evaluated predictors of response in patients with major depression treated with ECT	31 patients with major depression treated with at least six ECTs	Presence or absence of <i>DSM-III</i> melancholia did not predict response to ECT
Coryell and Turner (17)	1985	Evaluated efficacy of desipramine in patients with major depression over 6 weeks after a 1-week single-blind placebo period	Of 42 patients, seven had 30% decrease in depression scores; 35 patients received desipramine for at least 2 weeks	Presence or absence of endogenous diagnosis did not predict response to desipramine
Sauer et al. (18)	1986	Patients with major depression treated with amitriptyline for 3 weeks	Of 50 patients, 26 (52%) met <i>DSM-III</i> criteria for melancholia, 24 (48%) had endogenous symptoms according to Newcastle scale (score of 6 or higher)	No correlation between drug response and <i>DSM-III</i> melancholia or between drug response and absolute Newcastle score; trend for more improvement in patients with moderate Newcastle scores than in patients with low or high Newcastle scores
Georgotas et al. (19)	1987	Evaluated <i>DSM-III</i> melancholia and RDC and Newcastle endogenous depression; patients 55 and older treated with nortriptyline, phenelzine, or placebo for 6-7 weeks	Of 42 patients, 23 given nortriptyline and 19 given phenelzine	Presence or absence of RDC endogenous depression, <i>DSM-III</i> melancholia, or Newcastle endogenous depression did not significantly affect response rate
Paykel et al. (20)	1988	General practice patients with depression treated with amitriptyline or placebo over 6 weeks	141 patients treated for at least 4 weeks; about 30% had endogenous symptoms	No correlation between presence and absence of RDC endogenous symptoms, between sex and Present State Examination scores, or between endogenous-neurotic index and drug response
Davidson et al. (21-23)	1983, 1984	Evaluated efficacy of isocarboxazid versus placebo or two doses of isocarboxazid over 4 weeks in patients with depression	50 patients received isocarboxazid; 14 received placebo	Patients without endogenous/melancholic depression had a better response to isocarboxazid than those with endogenous/melancholic depression

it was questionable whether there are differences between patients who respond to placebo after 1 week and those who respond after 5 weeks. Nelson et al. (29) found that only one of 18 patients with *DSM-III* melancholia responded to the nonspecific effects of hospitalization but that 18 of 37 depressed patients without melancholia responded to hospitalization. They also found that 23 of 30 patients with melancholia compared with 12 of 20 patients without melancholia responded to desipramine.

Studies evaluating patients with and without endogenous/melancholic depression with respect to response to active medication versus placebo (30-38) have also yielded mixed results (table 8). Raskin and Crook (30) found that patients with endogenous depression re-

sponded favorably to chlorpromazine and imipramine but not to placebo. The criteria for endogenous depression in this study were not based on current classification systems. In a subsequent study, Paykel et al. (31) found that depressed patients with and without endogenous depression who were given either amitriptyline or phenelzine showed a statistically significant difference in responses to active medication versus placebo. Stewart et al. (32, 33) reported that among patients with RDC endogenous depression, 11 of 16 responded to desipramine and six of 17 responded to placebo; among patients with *DSM-III* melancholia, two of four responded to desipramine and none of seven responded to placebo. There was a trend toward a difference in response to active medication versus placebo among

TABLE 6. Studies That Evaluated Medication and Nonbiological Treatments Without Placebo Group in Depressed Patients With or Without Endogenous/Melancholic Depression

Study	Year	Design	Patients	Results and Comments
Prusoff et al. (24)	1980	Patients with major depression treated with pharmacotherapy (amitriptyline), interpersonal psychotherapy, combination of pharmacotherapy and psychotherapy, or nonscheduled control treatment	Of 81 patients, 26 had definite endogenous symptoms and 55 had either probable endogenous or no endogenous symptoms	Patients with endogenous symptoms had worse response to interpersonal therapy alone than did patients without endogenous symptoms; no difference between patients with and without endogenous symptoms for other three treatment conditions
Blackburn et al. (25)	1981	12-week trial assessed cognitive therapy, pharmacotherapy (amitriptyline or clomipramine), or combination of pharmacotherapy and cognitive therapy	Of 64 patients, 22 received cognitive therapy, 20 received pharmacotherapy, and 22 received combination	No difference between initial endogenous status and response to three treatments
Kovacs et al. (26)	1981	12-week trial assessed cognitive therapy versus pharmacotherapy (imipramine) in outpatients with depression	Of 44 patients, 19 received cognitive therapy and 25 received pharmacotherapy	Degree of endogenous features did not predict response to pharmacotherapy or cognitive therapy

TABLE 7. Studies That Primarily Evaluated Response to Placebo in Depressed Patients With or Without Endogenous/Melancholic Depression

Study	Year	Design	Patients	Results and Comments
Rabkin et al. (27)	1986	Evaluated patients with depression who had responded to single-blind placebo 3 months earlier	Of 45 patients, 20 remained well and 25 relapsed	Diagnosis of endogenous depression did not predict subsequent relapse
Fairchild et al. (28)	1986	Evaluated characteristics of 1-week single-blind and 5-week double-blind placebo response	16 patients who responded to 1-week placebo; five who responded to 5-week placebo; 34 who did not respond to placebo	More of the placebo nonresponders had an RDC diagnosis of endogenous depression
Nelson et al. (29)	1990	Evaluated patients with major depression after 1 week of hospitalization; patients who did not respond to hospitalization were treated with desipramine for 4 weeks	87 patients initially evaluated; <i>DSM-III</i> melancholia status was defined in 56; 52 patients required treatment with desipramine	More patients without melancholia responded to hospitalization; slightly more patients with melancholia responded to desipramine

patients with endogenous/melancholic depression, but the number of patients was too small to draw any conclusions. Rickels et al. (34) found that patients with endogenous depression displayed a trend toward different responses to active medication and placebo but that depressed patients without endogenous depression did not. (The diagnosis of endogenous depression was made by clinical judgment.) When Rickels et al. used *DSM-III* criteria for melancholia, they found that patients with and without melancholia did not differ in their response to active medication versus placebo. Zisook et al. (35) studied patients who had atypical depression and found that the presence of endogenous depression did not predict differential responses between active medication and placebo. Rabkin et al. (36) found that 41% of 1-week placebo responders, 52% of 6-week placebo responders, 49% of 6-week placebo nonresponders, 50% of 6-week active medication responders, and 42% of 6-week active medication nonresponders had endogenous depression. Fairchild and Rush (37) reported that 13 of 14 patients with endogenous depression responded to amitriptyline and that

four of nine patients with endogenous depression responded to placebo. Finally, Reimherr et al. (38) noted that in a group of patients with *DSM-III* melancholia, 64% responded to sertraline, 68% responded to amitriptyline, and 38% responded to placebo. In a group of patients without *DSM-III* melancholia, 58% responded to sertraline, 65% responded to amitriptyline, and 44% responded to placebo. Response was determined by a final CGI score of 1 or 2.

The results of our current study suggest that the presence of melancholic symptoms is associated with differential responses to active medication and placebo and generally predicts a poorer response to placebo. Therefore, there may be a greater need for antidepressant medication in the treatment of melancholic symptoms than nonmelancholic symptoms. Melancholic symptoms are not necessarily more predictive of a favorable response to somatic treatment, as evidenced by similar rates of complete or partial response to active medication for patients with melancholia (54%) and those without (61%).

One important reason for the lack of differentiation

TABLE 8. Studies That Evaluated Response to Active Medication and Placebo in Depressed Patients With or Without Endogenous/Melancholic Depression

Study	Year	Design	Patients	Results and Comments
Raskin and Crook (30)	1976	Retrospectively evaluated 880 patients treated in clinical trials with placebo, imipramine, or chlorpromazine	135 patients classified as endogenous	Endogenous patients responded well to imipramine and chlorpromazine but not to placebo; patients without endogenous symptoms showed no difference in response to three treatments
Paykel et al. (31)	1982	Evaluated response of depressed patients treated for 6 weeks	131 depressed patients treated with amitriptyline, phenelzine, or placebo	No significant differences in response to amitriptyline or phenelzine between patients with and without endogenous symptoms; both drugs were statistically superior to placebo for both groups
Stewart et al. (32, 33)	1983, 1985	Evaluated treatment response characteristics of patients with RDC endogenous depression (32) or <i>DSM-III</i> melancholia (33)	103 patients treated with either desipramine or placebo; same treatment group for both evaluations	More patients with endogenous depression and melancholia responded to desipramine than to placebo, but number of patients was too small to define statistical significance
Rickels et al. (34)	1985	Evaluated alprazolam versus doxepin, amitriptyline, and placebo in treating depression; then evaluated whether patients met <i>DSM-III</i> criteria for melancholia	504 outpatients with major depression began treatment; 348 classified endogenous and 143 classified nonendogenous; 154 had <i>DSM-III</i> melancholia and 338 did not	Group with endogenous depression seemed to show a difference between drug and placebo response; group without endogenous depression did not; <i>DSM-III</i> melancholia did not predict a greater difference between drug and placebo response
Zisook et al. (35)	1985	Evaluated isocarboxazid versus placebo in treating atypical depression	69 patients randomized to isocarboxazid or placebo; 24 (35%) had RDC endogenous depression	Presence of endogenous depression did not predict differential response to isocarboxazid versus placebo
Rabkin et al. (36)	1987	Evaluated effect of numerous factors on treatment response in patients with depressive illness	Pooled data on 484 patients from several studies; 143 1-week (N=94) and 6-week (N=49) placebo responders, 117 6-week placebo nonresponders, and 224 6-week drug responders (N=135) and 6-week drug nonresponders (N=89)	Presence or absence of endogenous diagnosis did not produce significantly different response rates in the five placebo or active medication groups
Fairchild and Rush (37)	1989	Patients with endogenous depression randomized to amitriptyline or placebo	Of 23 patients, 14 given amitriptyline and 9 given placebo	Most patients given amitriptyline responded; almost half of the patients given placebo responded
Reimherr et al. (38)	1990	Patients with major depression treated with sertraline, amitriptyline, or placebo for 6 weeks	Of 448 patients, 168 met <i>DSM-III</i> criteria for melancholia	Patients with melancholia had greater difference in active drug response versus placebo response than patients without melancholia. Both groups had statistically significant differences in active drug response versus placebo response

in response to drug versus response to placebo between melancholic and nonmelancholic patients in previous studies may be the severity of illness. Studies examining RDC endogenous depression and *DSM-III* melancholia noted that patients with endogenous/melancholic depression have more intense depression (21, 39, 40). Indeed, in our study, patients who met criteria for both

endogenous depression and melancholia had higher baseline Hamilton, Beck, CGI, and Raskin scores than patients who met neither (table 2). However, when we subdivided our patients into those with moderate or marked to severe depression, we found that patients who had *DSM-III* melancholia and moderate depression had the best response rates. These results are in line

with the work of Sauer et al. (18), Abou-Saleh and Coppen (41), Rao and Coppen (42), and Milln and Coppen (43). Abou-Saleh and Coppen (41) found that patients whose Newcastle endogenous depression scores were in the middle range responded significantly better than patients scoring in the upper range, who had more intense depression as indicated by higher Hamilton scores.

Our finding that moderately depressed patients responded better than severely depressed patients (particularly among patients with melancholia) is consistent with the work of Kocsis et al. (44), who found that moderately depressed patients had a 67% response rate and severely depressed patients had a 39% response rate in a sample of 132 subjects who were treated for 4 weeks with either amitriptyline or imipramine.

As noted in table 4, depressed patients without *DSM-III* melancholia did not show a difference between active medication and placebo (likely due to the small number of patients in each group), but there was a nonsignificantly higher rate of response to active medication than to placebo in the severely depressed group. This should not be taken to mean that drugs are ineffective for this patient group. There is evidence for a favorable response to antidepressants in the treatment of nonendogenous depression (45). Indeed, studies on patients with atypical depression who had primarily but not exclusively nonendogenous depression (32, 46, 47) have shown that there are notable differences between responses to active medication and placebo in such patient groups. These studies have also revealed that patients with nonendogenous depression plus anxiety, panic, or hysteroid dysphoria may preferentially respond to monoamine oxidase inhibitors over tricyclics (48–50), although this has not been confirmed by all studies (31, 51, 52). This evidence clearly supports the utility of drug therapy for nonendogenous depression, which generally is less severe than endogenous depression. However, other studies have shown that when the severity of depression falls below a minimal level (i.e., Hamilton score of 13–14), there may be no detectable difference between active medication and placebo (20, 32).

The findings of this study are not at odds with those in the literature reviewed here. As noted in table 4, depressed patients without melancholia had a nonsignificantly higher rate of complete or partial response to active medication than to placebo. Clearly, depressed patients with and without melancholia showed a response to antidepressant treatment, but the patients with melancholia displayed a much larger difference between their response to active medication and their response to placebo.

CONCLUSIONS

This study does not support the idea propounded in *DSM-III-R* that depressed individuals with melancholia are particularly responsive to somatic treatment. We found that depressed patients with *DSM-III* melanco-

lia did not respond to antidepressant treatment any better than did patients without *DSM-III* melancholia. Rather, it appeared that the patients with *DSM-III* melancholia showed a greater difference between their response to active medication and their response to placebo than the depressed patients without melancholia, particularly when the level of initial depression was of moderate rather than severe intensity. This finding suggests that patients who have *DSM-III* melancholia may be unresponsive to nonsomatic treatments. Future double-blind placebo-controlled trials are needed to assess the predictive validity of the endogenous/melancholic subtype.

APPENDIX 1. DSM-III and DSM-III-R Criteria for Major Depressive Episode With Melancholia and RDC for Endogenous Depression

DSM-III CRITERIA

The presence of at least five of the following:

1. Loss of pleasure in all or almost all activities
2. Lack of reactivity to usually pleasurable stimuli
3. At least three of the following:
 - a. Distinct quality of depressed mood
 - b. Depression usually worse in morning
 - c. Early morning awakening (at least 2 hours before the usual time)
 - d. Marked psychomotor retardation or agitation
 - e. Significant anorexia or weight loss
 - f. Excessive or inappropriate guilt

DSM-III-R CRITERIA

The presence of at least five of the following:

1. Loss of pleasure in all or almost all activities
2. Lack of reactivity to usually pleasurable stimuli
3. Depression regularly worse in morning
4. Early morning awakening (at least 2 hours before the usual time)
5. Marked psychomotor retardation or agitation (not merely subjective complaints)
6. Significant anorexia or weight loss (more than 5% body weight in a month)
7. No significant personality disturbance before first major depressive episode
8. One or more previous major depressive episodes followed by complete or nearly complete recovery

9. Previous good response to specific and adequate somatic antidepressant treatment

RDC

From groups A and B, a total of four symptoms for probable and six for definite, including one symptom from A:

Group A

1. Distinct quality of depressed mood
2. Lack of reactivity to usually pleasurable stimuli

3. Depression usually worse in morning
4. Loss of pleasure in all or almost all activities

Group B

1. Excessive or inappropriate guilt
2. Early morning awakening or middle insomnia
3. Psychomotor retardation or agitation
4. Poor appetite
5. Weight loss
6. Loss of interest or pleasure in usual activity or decreased sex drive

Initial Findings on Preventive Intervention for Families With Parental Affective Disorders

William R. Beardslee, M.D., Lizbeth Hoke, Ph.D., Ingrid Wheelock, B.A.,
Phyllis Clarke Rothberg, M.S.W., Polly van de Velde, M.S.W., M.P.H.,
and Susan Swatling, M.S.W.

Objective: The purpose of this study was to develop a clinician-based cognitive, psychoeducational, preventive intervention for families with parental affective disorder that would be suitable to widespread use, test its feasibility and safety, and define the areas affected by the intervention. The intervention was designed to increase understanding of parental illness and resilience in the children. **Method:** The authors studied the first seven families (14 parents) to receive the intervention. Enrollment criteria included affective disorder during the preceding year in at least one parent, presence of at least one child between the ages of 8 and 14 years who was not psychiatrically ill at the time of participation, and willingness to participate in the research study. The intervention consisted of parent, child, and family sessions. Assessment included semistructured interviews with parents about affective disorders, standard ratings of marital satisfaction and therapeutic alliance, and a recently developed semistructured interview to assess response to the intervention. **Results:** Overall satisfaction with the intervention was rated moderate to high by parents. No harm was reported. Ten of 14 parent subjects reported five or more behavior and attitude changes that they attributed to the intervention. The most frequent behavior and attitudinal changes reported were increased discussion of the illness and related issues and increased understanding of information about affective illness. **Conclusions:** The authors conclude that the intervention is safe and feasible in families with parental affective disorder.

(Am J Psychiatry 1992; 149:1335-1340)

A consensus from a variety of perspectives (1-4) supports the need for preventive intervention strategies for children of parents with affective disorders (5). As recent reviews have documented (6-9), there is compelling evidence that the children of parents with affective disorder fare more poorly than comparison samples whose parents have not experienced affective disorder. In particular, the children have high rates of depression as well as other areas of impairment.

Specific criteria have been identified for empirical research in prevention that have guided the design and implementation of this study (10, 11). These are 1) that the research involve clearly defined populations at risk, 2) that the risk be well-established, 3) that the interven-

tion be targeted to specific dimensions, 4) that it be expected to have a long-term effect, and 5) that evaluation be rigorous and use standard instruments (10, 11). In the development of new preventive strategies, Offord (11) has argued persuasively that it is essential to establish that the intervention does more good than harm. That was especially important in this project, since the intervention involved families not seeking treatment for their children. Thus, the possibility that it might be disruptive or harmful had to be considered seriously.

The aims of this investigation were to develop a clinician-based psychoeducational intervention that would be suitable for widespread use, test its feasibility and safety, and define the areas affected by the intervention. We have chosen to report on the first seven families receiving the intervention because the number is large enough to explore the safety and feasibility of the approach.

THE PREVENTIVE INTERVENTION APPROACH—SHORT-TERM, COGNITIVE, AND PSYCHOEDUCATIONAL

The intervention consists of six to 10 sessions and includes individual sessions with parents and children

Received March 27, 1991; revisions received Nov. 6, 1991, and Jan. 28, 1992; accepted Feb. 13, 1992. From the Department of Psychiatry, Children's Hospital and Judge Baker Children's Center. and one or two family meetings. The clinician is available to the family throughout the time of the intervention and thereafter by telephone. The core elements of the intervention are 1) assessment of all family members, 2) teaching of information about affective disorders and risks and resilience in children, 3) linking of this information to the individual's and family's life experience, and 4) enhancement of the child's understanding of the illness and development of concrete plans for helping the child cope in the future. The intervention has a strong cognitive orientation because cognitive approaches to treatment have proved successful in addressing the distortions of depression. Beardslee and Podorefsky's study (12) of the role of self-understanding in children growing up in homes with serious affective disorder also guided the design of the intervention. It emphasized the importance of self-understanding, in particular, being separate from their parents and able to take independent actions as essential dimensions of these children's ability to cope with and master the difficulties in living with a severely depressed parent. Eisenberg's observation (13) of the distinction between the diagnosis of disorder and the individual family's experience of illness provided an important conceptual frame. Our focus is on the illness experience. Given the heterogeneity of affective disorders in parents, it has proved essential to understand the child's and the family's specific experience of illness. Finally, our approach was designed for use by a wide range of practitioners who treat adults with affective disorder, especially general psychiatrists, internists, family practitioners, and pediatricians. The intervention has been described elsewhere (14), and a manual has been developed for training clinicians and for its implementation (available on request from the first author).

While there is evidence that children are at risk at every age, a target population of children ages 8–14 years was selected for this study because of the dramatic increase in the prevalence of affective disorders during adolescence. In addition, children in this age range begin to function autonomously and have the ability to understand causation in relation to the parental disorder.

METHOD

Design

Families were recruited from a prepaid health plan, local psychiatric hospitals, and general medical hospitals. The intervention was described as a research project that offered preventive intervention services and compared two forms of intervention. It was free and voluntary. Appropriate human studies permissions were obtained. Enrollment criteria for parents included a history of serious parental affective disorder in the recent past; at least one child, aged 8–14, not currently seriously disturbed; the absence of schizophrenia, organic brain damage, and current drug or alcohol addiction in the parents (although other psychiatric disorders

could coexist); the absence of a current life crisis; and the presence of a professional who was treating the adult affective disorder or could be involved should such treatment be necessary. Two-parent families are the subject of the current report, although the intervention has been used successfully with single-parent families. Families were randomly assigned on a two-thirds/one-third basis to a clinician-based psychoeducational, preventive intervention or to a lecture comparison group. A larger number of families were included in the clinician-based intervention because the evaluation of the safety of this intervention was a central aim of the initial study.

Implementation of the Intervention

Clinicians underwent an extensive training program to ensure that the intervention was delivered in a standard fashion. The training included a detailed review of transcribed cases, frequent meetings for supervision, and use of actors in a simulation of the intervention with videotaping for later review. In addition, ongoing supervision was provided.

Measures

Measures were administered separately to each parent by trained raters who were blind to any information about the intervention.

Adult psychopathology. The Schedule for Affective Disorders and Schizophrenia—Lifetime Version (SADS-L) (15) was employed to measure psychopathology in the parents before the intervention. It is a widely used interview that makes diagnoses according to Research Diagnostic Criteria (16). The validity of the SADS-L has been established in a wide range of studies.

Marital adjustment. The Dyadic Adjustment Scale (17), a self-report, was used to measure marital satisfaction and was completed by each parent before and after the intervention. The overall scale has demonstrated internal consistency and external validity (17).

Therapeutic alliance. We examined the therapeutic alliance in the family context using the Integrative Psychotherapy Alliance Scales (18). From the Integrative Psychotherapy Alliance Scales, two self-report scales were completed by each parent, assessing the individual's relationship with the therapist and the couple's relationship with the therapist as viewed by the respondent.

Semistructured interview about the intervention. A review of existing assessment literature revealed that several of the main dimensions targeted by our intervention, i.e., specific behaviors and attitudes that we hoped to change or modify, were not covered by existing quantitative instruments. We developed an interview designed to elicit both qualitative information about the experience of families and quantitative ratings by using 7-point Likert-type scales (19). Subsections assess the parent's prior factual knowledge of affective illness including risk factors for children and characteristics of resilient children, the parent's experi-

ence of illness in the family, the effect of the illness on the couple's relationship, the effect of the illness on the children, and concerns related to the illness. The postintervention assessment contains additional questions and self-rating scales about the parent's experience with the intervention and its helpfulness. The following four categories of ratings obtained from the semistructured interview about the intervention will be reported in this paper.

1. During the postintervention assessment, parents were asked to rate overall satisfaction with the intervention, the degree of helpfulness of the intervention in several areas (e.g., communication between parent and child concerning the illness, supportiveness of the spouse), and dissatisfaction or possible harmful effects.

2. During the pre- and postintervention interviews, parents were asked to identify up to three separate illness-related concerns. These concerns were then rated by the parent for degree of upset before and after the intervention; degree of helpfulness provided by the intervention was also rated. The ratings of concerns were modeled after the target problems approach (20) that has been used in psychotherapy research and that enables patients to identify and rate the unique problems they want to address in psychotherapy.

3. Scores of reported behavior and attitude changes that parents attributed at least in part to the intervention were obtained by examining the content of the pre- and postintervention interviews. The scoring system was developed for this study. Interrater reliability was established.

4. Self-ratings of functioning in the couples' and family relationships during the month before the interview were obtained before and after the intervention (e.g., degree to which couple's communication is disrupted by the affective illness, degree to which the affective illness has an impact on child-related tasks).

Subjects

The first seven families who completed the intervention form the cohort. The identified patients in the couples suffered significant affective disorder measured on the SADS-L (15), as indicated by the average lifetime duration of all forms of affective disorder, which was 10.2 years ($SD=15.3$). The shortest lifetime duration reported was 10 months. The lifetime diagnoses of these seven patients included bipolar I disorder ($N=2$; one also met criteria for schizoaffective disorder), major depressive disorder ($N=2$), and bipolar II disorder ($N=3$). In addition, the patients had associated nonaffective diagnoses. Moreover, within the past year, four identified patients were diagnosed with unipolar depressive disorders (one of these also had a diagnosed episode of schizoaffective disorder), two had bipolar II disorder (with an episode of depression), and one patient had bipolar II disorder but denied an episode in the past year, although the patient was still taking medication. There was a high rate of dual-parent lifetime illness. Both spouses in four couples (57%) had SADS-L diag-

noses (including anxiety and substance abuse disorders) at some point in their lifetime. All seven families fell within the top two socioeconomic levels on the Hollingshead-Redlich classification (21). The Dyadic Adjustment Scale provides an overall rating of marital adjustment that can be compared to available group norms. Our cohort of seven couples had a mean Dyadic Adjustment Scale score of 108.1 ($SD=12.7$), which falls below the scale's mean for married couples (mean=114.8, $SD=17.8$) but is substantially above the mean for divorced couples (mean=70.7, $SD=23.8$) (17). The mean age of children in the study was 10.9 years ($SD=2.0$) ($N=8$). Families had an average of one child in the age range.

RESULTS

Satisfaction and Safety

Average overall satisfaction (mean=5.29, $SD=1.73$) fell between moderately (scale value=4) and extremely (scale value=7) satisfied. Scores ranged from 1 (not at all satisfied) (1 parent) to 7 (extremely satisfied) (three parents). Mean satisfaction with the presentation of factual information during the intervention also was above the moderate level (mean=5.36, $SD=1.39$). Ratings varied from 3 ($N=2$) to 7 ($N=3$). Average scores for the more specific satisfaction ratings showed more variability, although most did not fall below the moderate level.

Ratings of therapeutic alliance provided an additional indication of overall satisfaction with the intervention. The mean individual alliance score for the 14 participants was 5.4 ($SD=0.8$) (possible range=1-7), and the mean couples alliance score was 5.5 ($SD=0.7$). Parents generally agreed with positive statements about the relationship of the therapist to the respondent (parent) and to the couple. No parent reported a negative therapeutic alliance, as indicated by a score of 3 or below.

Three postintervention 7-point Likert scales gave the parents the opportunity to rate the intervention directly for degree of dissatisfaction or harmfulness (1=not at all, 7=a great deal). Overall, parents reported no harm from the intervention. Means, standard deviations, and ranges were as follows: 1) Did the intervention make it more difficult to talk to your spouse about your illness: mean=1.21, $SD=0.4$, range=1 ($N=11$) to 2 ($N=3$); 2) Did the intervention make communication between you and your children worse: mean=1.0, $SD=0.0$; 3) Is your relationship with your children worse now that you have participated in the intervention: mean=1.36, $SD=1.34$, range=1 ($N=13$) to 6 ($N=1$). One parent in the same section gave a rating of 6 for making her relationship better with her children and a rating of 6 for making her relationship with her children worse. We believe that this was the parent's misunderstanding of the question because all of her other ratings of the intervention, including overall satisfaction, were positive, as were her husband's.

TABLE 1. Reported Changes in Behavior and Attitude/Cognitive Understanding in 14 Parents Who Received Preventive Intervention for Families With Parental Affective Illness

Area and Number of Changes Reported	N	%
Behavior		
0	2	14.3
1	3	21.4
2	3	21.4
3 or more	6	42.9
Attitude/cognitive understanding		
0	0	0.0
1	2	14.3
2	2	14.3
3	1	7.1
4 or more	9	64.3
Combined attitude and behavior		
0	0	0.0
1	1	7.1
2	1	7.1
3	2	14.3
4 or more	10	71.4

Self-ratings of couples and family functioning on the Dyadic Adjustment Scale and the semistructured interview about the intervention did not show significant change at postassessment.

Individual Concerns

On average, parents' degree of upset for the first and second illness-related concerns fell at the above moderate level (concern 1: mean=5.57, SD=1.40; concern 2: mean=4.50, SD=1.91). Mean postintervention degree of upset was 4.43 (SD=1.65) for the first concern and 3.86 (SD=1.35) for the second concern. Parents reported significantly less upset for the primary concern after the intervention (Wilcoxon matched-pairs signed ranks test: $T=23$, $p=0.04$). They also reported moderate help from the intervention for each of the concerns (concern 1: mean=3.86, SD=1.99; concern 2: mean=4.29, SD=2.13). All seven families cited concerns about their children as one of their three most pressing concerns. They were about evenly divided between worries about the future and immediate concerns about their children's responses to the affective illness.

Behavior and Attitude Changes

Eighty-six percent ($N=12$) of the parents reported at least one change in behavior that could be attributed to participation in the intervention, and 100% reported at least one change in attitude or belief about illness-related issues (table 1). Ten of the 14 parents reported at least four or more combined behavior and attitude changes. The most frequent behavior change reported by parents was increased discussion of the illness and related issues within the couple, among other family members, with children, and/or with persons outside the home. Attitudinal and cognitive changes most frequently reported were increased understanding of in-

formation about affective illness as it relates to the adult and risk and resilience factors in children. Some parents also reported that they believed their children better understood their illness. Several parents reported a sense of reassurance and destigmatization of the illness.

CASE REPORT

The family consisted of the mother, father, and three children: a 14-year-old girl who had been in residential care for the past 3 years, a 9-year-old boy, and a 2-year-old girl. The intervention took place in seven sessions, one with the family, one with the boy alone, and five with the couple. The mother, the identified patient, had suffered with depression since college. Throughout adulthood she had had recurrent episodes of dysthymia exacerbated by the stress of caring for her severely handicapped 14-year-old daughter. The mother's first psychiatric hospitalization occurred when her elder daughter became critically ill for a second time. Her son was then 4. Six months before the intervention, the mother had again become depressed. She had been placed on a regimen of medication and was being followed by a psychotherapist.

During the first two sessions, information on the couple's experience with the illness was obtained, first from the mother, then from the father, and finally from both parents' view of the child's experience. Each parent had separate concerns. These were similar to concerns expressed by other couples. The mother worried about the effects of her irritability and the consequences of her outbursts on her children. The father was concerned about the mother's prognosis and her continued need for medication. He also was concerned about the long-term effects of her depression on the children.

In an individual session the 9-year-old son demonstrated that he was aware of his mother's depression. He indicated that he worked hard to get his mother to feel happy, but he became sad when she was irritable. He wondered why his mother got so mad and how she had become ill. He had no symptoms of psychiatric disorder at the time of assessment.

The family session provided an opportunity for the mother, father, and son to talk about the illness and their perceptions of it. The mother talked about how she felt when she was depressed. The father talked about his strategy for managing and stated that he remained hopeful. The son had the opportunity to ask two questions that had been on his mind: how does one get depressed, and what is the link between the stress of his sister's needs and his mother's illness?

The family's illness experience had been complicated by the care requirements of the older sister. Because of the mother's sense of guilt, an open discussion had been avoided. The intervention provided the occasion for the family to talk openly about the mother's illness and the factors that exacerbated it. In follow-up assessment by a separate rater, the parents reported that the intervention had been helpful in several areas, including educating their son about depression and related issues, helping them feel less stigmatized by the illness, educating them about risk and resilience, and increasing their understanding of their son's experience of the illness.

DISCUSSION

The findings from the first seven cases indicate that the intervention is safe for these families. These findings

meet Offord's first tenet for a preventive intervention program (11), that the intervention do more good than harm. Families participating in the intervention had suffered severe and long-standing affective illness. They had experienced marital and family difficulties but had not sought help for their children at the time of their enrollment. It was clear that regardless of the severity of the illness, all of the parents were worried about their children. The main concerns identified in assessment were addressed by the intervention. There was a reported decrease in the degree to which parents were upset by these specific concerns. Positive therapeutic alliances were developed with the parents, as measured by the Integrative Psychotherapy Alliance Scales. Parents reported a moderate to high level of satisfaction with the intervention. They were more satisfied with the information given about depression and child resilience, and attention to concerns about their children, than they were with issues related to the couples' communication and taking perspective.

Ten of 14 individuals, most of whom had a current or past psychiatric disorder, reported four or more changes in attitude or behavior regarding their children, their illness, and their spouses. Families noted the benefits of openly discussing the illness. The intervention gave them the tools to discuss issues that had not been discussed before. Several parents reported that they felt able to talk to their children about their illnesses for the first time and to explore how their children felt about the difficulties.

Although parents reported several changes in specific behaviors and attitudes related to the affective illness, overall marital satisfaction, as measured by the Dyadic Adjustment Scale, did not change. Couples often discussed long-standing issues in their marriages that were related to the affective illness and that had not been discussed before. As suggested by Gottman and Krokoff's findings (22), positive changes in marital satisfaction and other areas of couples and family functioning may become more evident as parents have time to examine the issues raised during the intervention.

We hypothesize that profound family misunderstanding of affective disorder contributes to a lack of recognition of distress in children. The intervention is designed to increase family perspective taking, provide ways of enhancing competence in the children, and increase understanding of the illness experience. It is expected that the process started by the intervention will continue.

The appropriate design for evaluation of this intervention is a long-term longitudinal study with a large sample. This design is necessary because the incidence in children of new cases of disorder that might be prevented by the intervention is low. Hence, the possibility of demonstrating effectiveness in a short-term study is limited. Random assignment of subjects to intervention and comparison groups and objective measures of impairment and understanding are essential components for evaluation.

A clinician-based intervention used by practitioners

who are the first and often only contact for individuals with affective disorders must include primary, secondary, and tertiary prevention. It follows that an appropriate assessment strategy to determine the effects of this intervention should be to examine these three levels of prevention outcome. Expected primary prevention would be a lower incidence of disorder in children of families receiving intervention than in families not receiving intervention. Secondary prevention would be recognition of warning signs of distress and prompt referral. Tertiary prevention would be the family's recognition of disorder, especially depression, in the children and appropriate help-seeking behavior. The current study does not establish the effectiveness of the intervention.

There are limits to the initial findings. The cohort size is small and heterogeneous. The individuals conducting the intervention and the assessment were blind to information about either process, but it was impossible for the assessors not to know which families had received the clinician-based intervention. This was not expected to have a large effect because the findings of objective attitude and behavior changes involved minimal inference. Nonetheless, it will be important to explore additional ways of measuring change. Finally, this report does not establish the safety and feasibility of the intervention for all families but only for those enrolled in the study. Safety and effectiveness should be evaluated on an ongoing basis.

CLINICAL IMPLICATIONS

An important consideration is the range of families for whom this intervention is appropriate. It is designed to be used by clinicians who are the first contact for families presenting with parental affective illness. The small cohort does not allow specific definition of families for whom the intervention is most appropriate. Families in the midst of a life crisis or acute episode of parental illness were excluded. We believe that such families need treatment rather than preventive intervention. Similarly, children presenting with acute depression need appropriate pharmacologic and psychotherapeutic intervention. However, a large number of families do not have these acute conditions and are appropriate for preventive intervention.

An extensive literature of epidemiologic surveys and pediatric practices reports a large number of serious, untreated child psychiatric disorders (23, 24). There is also a substantial literature to suggest that the children of depressed parents who become depressed do not receive treatment. Keller and colleagues (25) found that in 38 cases of major depression in the children of depressed parents, only seven received any intervention. In terms of tertiary prevention, investigators studying suicide and its prevention have indicated the need for aggressive treatment of childhood depression (26, 27). The question of how to reach families in which untreated childhood disorder may exist, or in which dis-

order may develop, is an important one. This study offers a conceptualization of an approach and demonstration of safety that suggests promise for reaching children who are at risk through increasing family members' understanding of what they have experienced and how they can move on with their lives.

Depressive Illness Among Chemically Dependent Adolescents

Eva Y. Deykin, D.P.H., Stephen L. Buka, Sc.D., and Timothy H. Zeena, B.S.

Objective: The purpose of this study was to investigate the prevalence and correlates of depression among adolescents being treated for chemical dependence. **Method:** Using the National Institute of Mental Health Diagnostic Interview Schedule, the authors interviewed 223 adolescents, aged 15–19 years, who were in residential treatment for alcohol or drug dependence diagnosed according to DSM-III-R criteria. Data on sociodemographic characteristics, school and social performance, past history, family composition, familial alcohol and drug abuse, and previous victimization of the subjects were also gathered. **Results:** Fifty-four (24.7%) of the subjects met the DSM-III-R criteria for depression. Very few of the traditional correlates of depression discriminated depressed from nondepressed subjects, suggesting that the presence of chemical dependence overrides other predictors of depression. Only female gender, paternal psychopathology, and victimization (physical abuse, sexual abuse) emerged as important variables associated with depression. However, subjects whose onset of depression preceded their chemical dependence had different characteristics from those whose depression began after their chemical dependence. **Conclusions:** The prevalence of depressive illness in these chemically dependent adolescents was approximately three times that reported for nonreferred groups of similar age. This high rate of depression reflects the contributions of two distinct groups—those with primary depression and those with depression subsequent to chemical dependence—whose characteristics differed, suggesting the possibility of two pathologic processes, similar in manifestation but with different associated features and possibly with distinct etiologies. Confirmation of these findings in further research could indicate that the two forms of depression may require different treatment approaches.

(Am J Psychiatry 1992; 149:1341–1347)

Epidemiologic studies have confirmed clinical reports linking psychiatric morbidity with substance abuse in adult populations (1–4). Interest in comorbidity is sparked by the recognition that the presence or absence of psychiatric disorder may be an important means of subtyping substance abusers and could lead to refinement of the classification of both alcohol and drug abuse. Furthermore, the division of substance-abusing individuals into subgroups with and without additional psychiatric morbidity could elucidate different etiologic factors in the development of substance abuse and provide important information for group-specific treatment approaches. The connection of sub-

stance abuse and psychiatric illness is now well established in both referred and community adult populations. However, relatively little is known about the co-occurrence of psychiatric morbidity and substance abuse in adolescents. Although several investigators have reported the association of psychiatric symptoms with substance abuse in teen-age subjects, it is not clear to what extent such psychiatric symptoms reflect an actual diagnostic entity (5–7). In a previous study of the co-occurrence of depressive illness and substance abuse in 424 college freshmen (8), we found that alcohol abuse was associated with major depressive disorder only, while drug abuse was associated with major depressive disorder and other DSM-III diagnoses as well. However, the relatively low frequency of these psychiatric diagnoses in the college population made it difficult to examine specific correlates of the observed associations.

A study of the possible interconnection of substance abuse and psychiatric illness during adolescence could have important implications for prevention and treatment. Adolescence is a pivotal stage of human development, posing simultaneous challenges in the cognitive, psychological, and social spheres. If mastery of these

challenges is impaired by psychiatric illness, deleterious consequences may be more likely to occur than if psychopathology begins in adulthood. Focusing study on the adolescent rather than the adult may facilitate the identification of risk factors that are more proximal to the onset of psychiatric illness. In addition, the temporal sequence of chemical dependence and psychiatric morbidity may be easier to determine in adolescence, when the two have not yet become so intertwined that it is nearly impossible to determine which is primary.

In this study we examined the prevalence and correlates of major depression among adolescents who were receiving inpatient treatment for dependence on alcohol, drugs, or both. Depression was specifically chosen for study because of its reported association with substance abuse in adulthood and because epidemiologic data have indicated a progressive increase in the incidence of depression during adolescence among cohorts born after 1935 (9, 10). These are the birth cohorts that have also experienced increased use of alcohol and, more recently, drugs. In addition, we chose depression because its subjectively painful symptoms could trigger repeated self-medication, leading to substance abuse. Conversely, depression could also result from the social difficulties caused by heavy use of alcohol and drugs or by the action of drugs that depress the CNS. By selecting a study group of chemically dependent adolescents, we removed substance abuse as a potential confounding factor, permitting a less obscured examination of other possible etiologic variables in the development of depression.

The purpose of this study was threefold: to assess the prevalence of depression diagnosed according to *DSM-III-R* in a group of adolescents undergoing treatment for chemical dependence, to examine potential correlates of depression in this population, and to investigate, among those subjects who met the criteria for depression, whether depression preceded or followed chemical dependence.

METHOD

The 223 study subjects (168 male and 55 female) were drawn from seven of the eight residential treatment centers for substance-abusing adolescents funded by the Massachusetts Department of Public Health, which underwrote the cost of approximately half of the hospital beds. Funding for most of the other patients came from state revenues (Medicaid, the Department of Social Services, or the Department of Youth Services); only a few subjects were covered by private insurance. The eighth treatment center chose not to participate in the study. The seven participating facilities contained a representative population of adolescents whose treatment was supported by public funds.

The treatment sites drew patients from the entire state. Three sites treated both male and female patients, three accepted only male patients, and one accepted only female patients. The length of treatment ranged

from 3 to 18 months. All treatment programs were modeled on the Alcoholics Anonymous/Narcotics Anonymous 12-step program, which focuses on group discussions, assigned tasks, and well-defined, graded levels of responsibility as the core of treatment. Academic work was also compulsory for subjects who had not finished high school.

To be eligible for participation in the study, subjects had to be 15–19 years of age, meet the *DSM-III-R* criteria for dependence on alcohol, drugs, or both, and sign an informed consent form. For subjects under age 18 who were not legally empowered to make their own health care decisions, signed parental consent was also obtained. The study was approved by the institutional review boards of the Harvard School of Public Health and the Massachusetts Department of Public Health and by the directors of the treatment centers. Eligible subjects were enrolled in the study between the second and fourth weeks of treatment. We compared the age, sex, and race distributions of enrolled subjects with those of subjects who chose not to participate and found that there were no differences between the two groups. This suggests that the enrolled subjects were representative of young patients entering treatment at the sites.

Information leading to the establishment of psychiatric diagnoses was obtained with the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (11), version III-R, administered by research assistants trained in the use of this instrument. The research assistants were college graduates who had previous experience working with adolescents. Training in the use of the DIS consisted of approximately 50 hours of classroom instruction, trial interviews, homework assignments, field experience under supervision, and, finally, training interviews with adolescents who were not entered in the study. Staff meetings were held regularly to resolve any ambiguities that had been encountered during the interviews and to ensure that there had not been any drift from the established protocol.

The DIS was specifically designed for persons aged 18 and over. However, we had previously used this interview with 16- and 17-year-olds and found that respondents understood the questions well and had no difficulty providing the required information (12). Similarly, our experience with the current study group indicates that the DIS works equally well with persons as young as 15. The only diagnosis that could not be established in our group of subjects was that of antisocial personality disorder, which can be ascertained only for persons over the age of 18.

We obtained data on the subjects' background characteristics, family composition, school and social performance, work history, familial substance use, and history of victimization by means of the Family and Social History Interview, a structured interview based on the Winters Adolescent Diagnostic Interview (13) but substantially expanded and changed to meet the needs of this study.

Administration of the DIS and the Family and Social

^aNumber of subjects on which percents for individual items are based varies slightly because of missing data on some items for some subjects.

History Interview took about 2 hours. Data obtained by the DIS were scored on a personal computer with the use of a scoring program we developed to generate a profile of *DSM-III-R* axis I diagnoses for individual subjects as soon as their DIS data are entered in the computer. The diagnoses generated with the personal computer data scoring program were identical to those generated by the standard mainframe scoring program. (Information on the personal computer scoring algorithm is available from the first author on request.)

Data were analyzed with an SAS program (14). Odds ratios and 95% confidence intervals were calculated for male and female subjects separately to assess the association of depression with several potential correlates. Summary estimates for the total group were also calculated, controlling for gender, by the Mantel-Haenszel summary odds ratio (15). The odds ratio quantifies the association of two variables. Odds ratios equal to 1 indicate that the variables are independent of each other, whereas those above and below 1 indicate positive and negative associations, respectively. The greater the departure from 1, the null value, the stronger the association.

RESULTS

The mean age of the subjects was 16.5 years (SD=1.1). Table 1 shows other sociodemographic characteristics of the study group, which overall was representative of a disadvantaged group. Families of more than half of the subjects had received some form of welfare assistance (Aid to Families With Dependent Children, food stamps, Medicaid, fuel assistance, subsidized housing). More than one-third of the subjects had been retained in the same school grade for 2 or more years. The education deficit was particularly pronounced among the male subjects, who were three times as likely as the female subjects to be substantially behind in school. The proportion of nonwhite subjects in the study (15.2%) was only slightly higher than the

proportion of the minority population of Massachusetts (12%) reported by the 1990 census.

All subjects met the *DSM-III-R* criteria for alcohol or drug dependence, and 86.1% met the criteria for both (table 1). A total of 54 subjects met the *DSM-III-R* criteria for major depression. The lifetime prevalence of depression was 24.7%, with the prevalence among females more than 2.5 times the prevalence among males—a highly significant difference. The prevalence of depressive illness among these chemically dependent adolescents was between two and four times the prevalence that has been found in clinical samples of comparable age in studies that have used the DIS to diagnose psychopathology. In our previous study of college students aged 16–18 years (8), we found that 8.2% met established criteria for major depressive disorder. Although the prevalence of depression among the college students was only one-third as high as that in the present study, the ratio of depressed females to depressed males (2.5:1) was similar to that in the present study. Furthermore, in a recent report, Burke et al. (16) applied life table survival analysis techniques to the Epidemiologic Catchment Area (ECA) study data to estimate the prevalence of depressive illness in a community sample at various ages. The authors found that 4.4% of the females and 2.4% of the males had experienced at least one episode of depressive illness before the age of 20. Despite the variation in the estimates of the prevalence of depression, the twofold greater risk for females was consistent among the college students, the ECA sample, and the adolescents in this study.

Apart from gender, a number of other sociodemographic characteristics have been identified as possible correlates of depression (17). Among these are living apart from natural parents, school failure, low socioeconomic status, parental psychopathology, and victimization (18–22). To test whether these and similar factors increased the risk of depression in a chemically dependent population, we assessed the association of selected sociodemographic, family history, and victimization characteristics with depression.

^aNumber of subjects on which percents for individual items are based varies slightly because of missing data on some items for some subjects.

^bMantel-Haenszel summary odds ratio, controlled for gender.

None of the sociodemographic characteristics we studied had a statistically significant association with depressive illness (table 2). Perception of low socioeconomic status was the only variable that indicated even a modest elevation in the risk of depression for both sexes. Most of the other sociodemographic variables had a paradoxically different relationship with depression for the male and female subjects: variables that were positively associated with depression among females were negatively associated among males, and vice versa. However, because all associations were very close to the null value, and none was statistically significant, this paradoxical effect probably represents random variation. Overall, our examination of sociodemographic variables and depression in this study group does not support the findings of previous studies.

Table 3 presents the data on the association of depression with familial alcohol abuse, familial drug abuse, and reported history of emotional or psychological problems in the subjects' first-degree relatives. Parental alcohol abuse has long been associated with depressive symptoms in children, and therefore familial alcohol and drug abuse were assessed for a possible link with depression. Similarly, parents' psychopathology,

especially depressive illness, has also been reported to increase the risk of depression in their children (23). We obtained histories of familial alcohol and drug abuse and psychopathology by interviewing the subjects rather than by direct examination of parents and siblings. Subjects were asked, "Did your (mother/father/siblings) ever have a psychological, emotional, or mental problem?"

Alcohol abuse by the mother was reported by about one-third of the subjects, alcohol abuse by the father was reported by almost two-thirds of the subjects, and alcohol abuse by siblings was reported by about one-fourth of the subjects (table 3). Drug abuse by the mother was reported by almost one-fourth of the subjects, drug abuse by the father by almost half, and drug abuse by siblings by nearly one-fourth. Although fathers were more likely than mothers to have histories of alcohol or drug abuse, they were less likely to be identified as having a psychological problem. With the exception of paternal psychopathology, the high frequency of familial substance abuse and psychopathology did not consistently elevate the risk of depressive illness.

Several investigations have reported an association

between child abuse/neglect and subsequent depressive manifestations or suicidal behavior (22–25). Because of this reported link, we examined whether prior victimization was related to depressive illness. Victimization was assessed by asking subjects four separate questions: whether they had ever been physically abused, whether a report of child abuse/neglect had ever been filed on their or their siblings' behalf, whether they had ever been sexually abused, and whether they had ever been removed from their home by state authorities. Table 4 shows that nearly all indicators of victimization increased the risk of depression, irrespective of gender. Of the four types of victimization, physical abuse was associated with the highest risk of depression; its association with depression was statistically significant for the female subjects ($\chi^2=6.2$, $df=1$, $p=0.01$) and for the entire study group when gender was controlled ($\chi^2=8.8$, $df=1$, $p<0.01$). Compared to the nondepressed subjects, depressed male subjects were 1.5 times more likely and depressed female subjects were 5.6 times more likely to have experienced physical abuse. Sexual abuse, which was endemic among the female subjects, more than doubled the risk of depression; sexual abuse of the male subjects increased their risk of depression by only 40%. However, the increased risk of depression was not great enough to be statistically significant for either sex. Removal of the subject from the home by authorities was a risk factor for depression among the female subjects only.

Of the three categories of risk factors—sociodemographic, familial substance abuse and psychopathology, and victimization—only victimization appears to have been a consistent risk factor for depressive illness in this group of chemically dependent adolescents. Both gender and paternal psychopathology continued to be significantly related to depressive illness at the $p<0.05$ level. However, after adjusting for these variables, we found that history of physical abuse fell just short of statistical significance (odds ratio=2.0; 95% confidence interval=0.9–5.1). The independent association between physical abuse and depression was partly due to the link between gender, paternal psychopathology, and depression. The three variables that were independently associated with depression for the whole group of subjects (gender, paternal psychopathology, and physical abuse) were examined simultaneously in a

logistic regression model predicting depression, and although all three continued to show an association with depression the association was significant only for the first two.

Because depressed and nondepressed adolescents appear to be similar on many variables, we further assessed whether the depressed subjects had histories of more severe substance abuse by comparing the mean ages at which the two subgroups of subjects became chemically dependent and the number of substances they had used. Overall, the depressed subjects developed chemical dependence at an earlier age (mean=11.8 years, $SD=2.3$) than did the nondepressed subjects (12.7 years, $SD=1.9$), and the depressed subjects used a slightly higher number of substances (mean=4.1, $SD=2.3$, versus mean=3.7, $SD=2.0$). The younger age at the development of chemical dependence was statistically significant only for the male subjects (mean=11.5 years, $SD=2.1$, versus mean=12.6 years, $SD=2.1$; $t=2.4$, $df=166$, $p=0.02$), and the larger number of substances used was significant only for the female subjects (mean=4.1, $SD=2.6$, versus mean=2.9, $SD=1.9$; $t=1.96$, $df=53$, $p=0.05$).

The temporal sequence of depression and severe substance abuse in adolescence is an area that has not been examined previously, and it is one that poses inherent methodologic difficulties. A major problem is determining when an individual passes from a nonpathologic state to a pathologic one. Specifically, it is difficult to differentiate the moment at which symptoms become a syndrome. To examine the sequence of chemical dependence and depression among the 54 depressed subjects, we compared the ages at which each subject first met established criteria for depressive illness and for chemical dependence. Three time patterns of comorbidity were possible: depression followed by chemical dependence, depression preceded by chemical dependence, and both occurring at approximately the same time. Because we adhered to stringent *DSM-III-R* criteria for diagnosis, we cannot exclude the possibility that prodromal characteristics—such as depressive symptoms or dysphoria in the case of depression or substantial alcohol or drug use in the case of chemical dependence—may have occurred before the age at which full *DSM-III-R* criteria for the two disorders were met. Onset of depression was designated as the age at which a

TABLE 5. Temporal Sequence of Depression and Chemical Dependence Among 51 Depressed Adolescent Subjects

Variable	Depressed Subjects					
	Male		Female		Total	
	N	%	N	%	N	%
Depression occurred first	8	44.4	10	55.6	18	35.2
Chemical dependence occurred first	15	68.2	7	31.8	22	43.1
Both occurred at same time	3	27.3	8	72.7	11	21.6
Total	26	51.0	25	49.0	51	100.0

subject met all criteria for depressive illness. Similarly, onset of alcohol or drug dependence was defined as the earliest age at which all criteria were met.

Table 5 shows the temporal sequence of depression and chemical dependence for 51 of the 54 depressed subjects. We were not able to establish the temporal sequence for three subjects and thus did not include them. The male subjects were twice as likely as the female subjects to have the onset of depression follow chemical dependence, whereas females were more likely to have depression as the primary disorder or to have it co-occur with chemical dependence. Due to the small subgroup sizes in this analysis, the difference between males and females fell just short of statistical significance ($\chi^2=5.37$, $df=2$, $p=0.08$). Regardless of whether depression preceded or followed chemical dependence, the female subjects became depressed at an earlier age. The greatest difference between male and female subjects in age at onset of depression was among those whose depression preceded chemical dependence (2.6 years), but the difference was evident in a more muted form (0.6 years) even among those whose chemical dependence occurred first.

Because the sequence pattern of depression and chemical dependence differed for the two sexes, we examined other variables to determine whether any were associated with a specific pattern of comorbidity. The 51 depressed subjects were divided into three subgroups designated by the patterns of the temporal sequence of depression and chemical dependence. The 18 subjects who experienced depression first were compared to the 22 subjects whose depression followed chemical dependence with respect to the sociodemographic, familial, and victimization variables shown in tables 2-4. The 11 subjects for whom depression occurred at the same time as chemical dependence were eliminated from this analysis. Odds ratios of 1.8 or more were deemed to suggest an association with a specific pattern of comorbidity. Table 6 lists the variables associated with each of the two sequences of comorbidity. Subjects for whom depression was the primary disorder had characteristics that have traditionally been considered correlates of depressive symptoms in adolescence, namely, female gender, emotional/psychiatric problems in a parent, and victimization. Conversely, substance abuse by first-degree relatives and poor academic performance were the salient characteristics of

TABLE 6. Variables That Differentiated Temporal Sequences of Depression and Chemical Dependence Among 51 Depressed Adolescent Subjects

Variable	Odds Ratio
Subjects with onset of depression before onset of chemical dependence (N=18)	
Female gender	2.8
Psychological problem in mother	2.2
Drug problem in father	2.3
Child abuse report filed	3.4

Drug problem in siblings	5.5

the subjects whose depression developed only after chemical dependence.

DISCUSSION

The findings of this study suggest that among chemically dependent adolescents, depressive illness may consist of an admixture of two forms. One form, affecting a relatively small number, is primary depression with associated features that are known correlates of affective disorder. The other form, present in a larger number of subjects, is depression secondary to chemical dependence with associated features characteristic of severe substance abuse. Although these two forms taken together constituted an extremely high occurrence of depression overall (24.7%), if one considers only primary depression, the prevalence diminishes to only 8.1% (18 of 223 subjects). This rate of primary depression is similar to the 8.2% found in our study of college students (8) and to the 8.6% reported by Kandel and Davies (26) in their study of severe depressive symptoms in a group of nonreferred adolescents. The concordance of these three rates could imply that the excessive rate of depressive illness seen in the present study represents two separate pathologic processes, with substance abuse as the etiologic factor for secondary depression. This explanation is further supported by the lack of differentiation of depressed and nondepressed subjects with respect to the traditional risk factors for depression. If there are two forms of depression, each with separate associated characteristics, when depressed subjects are compared to nondepressed subjects, the known risk characteristics for depression will be muted.

The obscuring of differences between depressed and nondepressed subjects was evident in this study. Only a few variables—female gender, paternal psychopathology, and a history of physical abuse—independently emerged as statistically significant in differentiating subjects with and without depression. In addition,

other components of victimization—sexual abuse and a history of a report of child abuse—also increased the risk of depression but fell short of statistical significance. We propose that victimization is not simply a confounding factor in the relation between gender and primary depression, since the association between victimization and depression remained strong even when gender was controlled. The independent effect of victimization suggests two possible explanations. Children exposed to abuse may incorporate the negative opinions conveyed by the abusers and are thus likely to have diminished self-esteem. In addition, if the abuser is a parent or primary caretaker, the child is denied the opportunity for solace, which is necessary in order to develop appropriate adaptive mechanisms. Low self-esteem and the inability to respond to adverse events are suspected components of depressive illness. Furthermore, if abuse necessitates the removal of the child from the home, disruptions of bonding may occur, making the child more vulnerable to subsequent psychopathology.

Data from this study have shown that among adolescents undergoing treatment for chemical dependence, the rate of depression is approximately three times that among persons of similar age who have not been referred for medical treatment. Part of this high rate may be the result of Berkson's bias (27). This bias produces an overestimate of comorbidity, since persons who enter treatment are more likely to do so if they suffer from more than one condition. Therefore, clinical samples will have higher rates of comorbidity than samples drawn from the community. The extent to which Berkson's bias operated in this study cannot be quantified, but it is perhaps less than in other clinical samples because a sizable proportion of the adolescents studied did not choose to obtain treatment, having been remanded to the treatment sites by court orders.

Despite the possibility of an overestimate of the prevalence of depression, the findings suggestive of two forms of clinical depression open a challenging area of investigation, which could possibly lead to a refinement of disease classification and have important implications for treatment. Patients with primary depression who are chemically dependent might well profit from treatment directed at their depression rather than at their chemical dependence. Conversely, those who become depressed after they have developed chemical dependence might show greatest improvement when treatment is targeted at their alcohol and drug abuse rather than at their depression.

Resident Physician Substance Use, by Specialty

Patrick H. Hughes, M.D., DeWitt C. Baldwin, Jr., M.D., David V. Sheehan, M.D.,
Scott Conard, M.D., and Carla L. Storr, M.P.H.

***Objective:** This study compares substance use by medical specialty among resident physicians. **Method:** The authors estimated the prevalence of substance use of 11 medical specialties from a national sample of 1,754 U.S. resident physicians. **Results:** Emergency medicine and psychiatry residents showed higher rates of substance use than residents in other specialties. Emergency medicine residents reported more current use of cocaine and marijuana, and psychiatry residents reported more current use of benzodiazepines and marijuana. Contrary to recent concerns, anesthesiology residents did not have high rates of substance use. Family/general practice, internal medicine, and obstetrics/gynecology were not among the higher or lower use groups for most substances. Surgeons had lower rates of substance use except for alcohol. Pediatric and pathology residents were least likely to be substance users. **Conclusions:** The authors' previous research indicates that residents overall have lower rates of substance use than their age peers in society. Yet resident substance use patterns do differ by specialty. Residents in some specialties are more likely to use specific classes of drugs, to use a greater number of drug classes, and to be daily users of alcohol or cigarettes.*

(Am J Psychiatry 1992; 149:1348-1354)

The ready availability of dependence-producing substances poses an occupational risk to physicians and other health professionals, but this risk does not appear to be evenly distributed among the medical specialties. Data from drug treatment programs, medical licensing boards, and surveys of physicians suggest that members of certain specialties are at greater risk of substance use.

Studies of treated populations include Bissell et al.'s follow-up of 98 male and 95 female physician members of Alcoholics Anonymous (1, 2). Using known specialty distributions for U.S. physicians, Bissell et al. found male and female psychiatrists to be overrepresented and observed a similar tendency for female physicians in emergency medicine. Surgical specialties were underrepresented. Morse et al. (3) reviewed 73 chemically dependent physicians treated at the Mayo Clinic and found that family/general practitioners and, to a lesser

extent, anesthesiologists were overrepresented. Talbott et al. (4) described 1,000 physicians treated at Smyrna, Ga., 92% of whom had a primary diagnosis of chemical dependence. Anesthesiologists, thoracic surgeons, emergency medicine practitioners, plastic surgeons, and family/general practitioners were overrepresented. Pediatricians and pathologists were underrepresented.

State licensing boards are another source of data on physician substance abuse. In a study of 34 physicians disciplined by the Oregon board, Shore (5) reported that psychiatrists were overrepresented when compared to the expected rate among registered physicians in that state. Ikeda and Pelton (6) studied 247 physicians enrolled in the California Diversion Program; over 90% were being treated for substance abuse. Three specialties—anesthesiology, emergency medicine, and family/general practice—were overrepresented.

Survey researchers have also investigated drug use in medical specialties. Sethi and Manchanda (7) interviewed 240 resident physicians in India but did not compare drug use rates by specialty. McAuliffe et al.'s questionnaire survey (8) of 489 physicians selected from the Massachusetts Medical Society membership found psychiatrists to have much higher rates of use for all types of substances, followed by anesthesiologists. Maddux et al. (9) found psychiatry residents at a Texas medical center more likely than residents in other specialties to report benzodiazepine use in the past year. Myers and Weiss (10), in a survey of 1,805 interns and

residents in Ontario, Canada, found that anesthesiology and psychiatry ranked among the first five of 11 specialties for each of three patterns of substance use. Community health residents were least likely to use substances, followed by residents in emergency medicine, surgery, and pediatrics. Moore et al. (11) followed 1,014 graduates of Johns Hopkins School of Medicine and found no statistically significant differences in rates of alcohol abuse in the major specialties.

In the preceding studies, physicians in anesthesiology, emergency medicine, family/general practice, and psychiatry were found to be at higher risk of substance use or abuse than physicians in other specialties, but these findings were not consistent across the various studies. This raises the question of possible biases due to inadequate or nonrepresentative samples, especially when studies are confined to physicians in a single medical center, state, or treatment program.

To further explore drug use differences by medical specialty, we examined data from a national survey of U.S. resident physicians (12). The survey provided data on drug use patterns in 11 medical specialties. The aim was to identify those specialties which were at greatest risk of 1) unsupervised use of specific drug classes or types, 2) multiple drug use, and 3) daily substance use, as well as 4) legitimate use of controlled substances under the supervision of another physician. Background variables were examined to determine if observed differences in substance use patterns might be explained by factors other than specialty status.

METHOD

The study sample was drawn from the American Medical Association physician master file, which is considered the most comprehensive listing of U.S. physicians available. The sampling frame consisted of 15,814 U.S. physicians in their third year of residency training who had graduated from medical school in 1984. The 3,000 subjects were a stratified random sample selected to ensure that their distribution by major specialty reflected that of the master file. The 11 specialties were anesthesiology, emergency medicine, family/general practice, internal medicine (including subspecialties), obstetrics/gynecology, pathology, pediatrics, psychiatry, radiology, surgery (including subspecialties), and a category for those who were in another specialty or who were undecided.

In the spring of 1987, each subject was sent an anonymous questionnaire, a cover letter with a \$1 incentive, and a response postcard (with subject identification number) to be returned separately. The eight-page, multiple-choice questionnaire was designed for an optical mark reader and took 15–25 minutes to complete. Up to two follow-up questionnaires were sent to subjects whose postcards were not returned.

Questions covered demographic characteristics, medical specialty, work activities, and drug use. Respondents were asked how frequently they had used each of 11 types

of drugs in their lifetime, in the past year, and in the past 30 days. Substance categories included cigarettes, alcohol, marijuana, cocaine, LSD, other psychedelic drugs, heroin, and prescription drug types including amphetamines, barbiturates, benzodiazepines, and opiates other than heroin. Questions on prescription drugs included the phrase "without a doctor telling you to use them." The questions were based on the National Institute on Drug Abuse's Monitoring the Future study at the University of Michigan Institute for Social Research in Ann Arbor in order to allow comparison with a sample of similar age (13). Drug use questions had been field tested on medical students in earlier pilot work (14, 15).

The overall response rate was 60% (N=1,785). Of these, 1,754 indicated current specialty and were used for this analysis. Distribution of specialties among respondents reflected the actual distribution of residents in specialty training programs for the year of the survey (16). The drug use prevalence rate of each specialty was compared to that of all others combined. Statistical significance was evaluated by using the chi-square test for stratified samples (one degree of freedom) and 95% confidence intervals.

RESULTS

Are Residents in Some Specialties More Likely to Use Specific Types of Substances?

The proportion of residents in each specialty who had ever used 10 of the 11 substances in their lifetime appears in table 1. Heroin users were too few to draw firm conclusions regarding specialty differences, and therefore the data are not shown.

Use of nonprescribed substances. Little variation was observed across specialties in relative ranking of the legal and illicit substances used. This trend held for both lifetime (table 1) and past year (figure 1) substance use. Residents in all specialties reported alcohol as the most widely used substance. Over 90% of residents in each specialty reported having used alcohol in their lifetime and in the past year, and more than 80% in each specialty reported use in the past month. Among the nonprescribed substances, marijuana was the second most frequently used substance for all the specialties, cigarettes were third, cocaine fourth, and psychedelics fifth (figure 1).

The following five specialties had substance use rates close to the mean for all residents: anesthesiology, internal medicine with its subspecialties, surgery with its subspecialties, radiology, and those signifying "other." Psychiatry and emergency medicine residents showed higher rates of drug use than did other specialties. Psychiatry residents had the highest rates for lifetime-ever use of marijuana (prevalence=80.7%, 95% confidence interval=72–89, $p=0.002$), cigarettes (prevalence=65.5%, 95% confidence interval=55–76, $p=0.008$), cocaine (prevalence=45.5%, 95% confidence interval=35–56, $p=0.001$), LSD (prevalence=30.7%, 95% confidence interval=21–40, $p=0.0001$), and other psychedelic sub-

stances (prevalence=30.7%, 95% confidence interval=21-40, $p=0.0001$). Psychiatry also had the highest percentage of marijuana users in the past year (prevalence=34.1%, 95% confidence interval=24-44, $p=0.0001$). Emergency medicine had the highest rate of cocaine use in the past month (prevalence=8.0%, 95% confidence interval=1-16) and the past year (prevalence=14.0%, 95% confidence interval=4-24) and high use rates in the past year for marijuana (prevalence=28.6%, 95% confidence interval=16-41, $p=0.03$) and cigarettes (prevalence=16.3%, 95% confidence interval=6-27).

Specialties with lower rates of nonprescribed substance use included family/general practice, obstetrics/gynecology, pediatrics, and pathology. Family/general practice residents had the lowest rate of ever having used cocaine (prevalence=17.6%, 95% confidence interval=13-22, $p=0.0001$) and psychedelic substances (other than LSD) in their lifetime. Obstetrics/gynecology had the lowest lifetime-ever rate of cigarette use. Pediatric residents had the lowest lifetime-ever use of marijuana (prevalence=55.9%, 95% confidence interval=49-63, $p=0.006$) and alcohol (prevalence=93.8%, 95% confidence interval=90-97, $p=0.002$). Pathology residents dropped from the third highest rate of lifetime-ever cigarette use to the lowest rate in the past year and past month. Pathology residents also reported the lowest rate of past year use of cocaine and marijuana.

Unsupervised use of prescription drugs. Little cross-specialty variation was also observed in relative ranking of the prescription drug types by lifetime (table 1) or past year (figure 2) use. Residents in all specialties reported higher rates of unsupervised use of benzodiazepines and amphetamines than of barbiturates and prescription opiates. Rates of amphetamine and prescription opiate use in the past year were low (4.7% or lower for all specialties), and past year use of barbiturates was negligible. Benzodiazepines, however, were clearly the preferred type of prescription drug for all

specialties; 9.4% of all residents had engaged in unsupervised use of benzodiazepines in their lifetime.

Specialties that showed higher rates of unsupervised use of prescription substances included anesthesiology, with the second highest lifetime use of amphetamines (prevalence=29.6%, 95% confidence interval=21-38, $p=0.02$), and pathology, with the highest lifetime use of prescription opiates. Psychiatry had the highest lifetime and past year rates for both benzodiazepine and amphetamine use (benzodiazepines: lifetime prevalence=50.0%, 95% confidence interval=40-60, $p=0.0001$; past year prevalence=27.3%, 95% confidence interval=18-37, $p=0.0001$). Emergency medicine residents were the second most likely to have used benzodiazepines in their lifetime and in the past year, but the rates were nearly half those of psychiatry. Surgeons tended to report lower rates of use for all prescription substances and were among the specialties least likely to have used benzodiazepines in their lifetime (prevalence=16.4%, 95% confidence interval=12-21, $p=0.008$), along with pediatric residents (prevalence=16.4%, 95% confidence interval=11-22, $p=0.008$). Pathology residents tended to have lower rates of use in the past year for all prescription drugs except benzodiazepines.

Are Residents in Some Specialties More Likely to Be Multiple Drug Users?

The mean number of drug types used by respondents in each specialty was calculated for past month, past year, and lifetime use in order to address this question. All 11 substance types were counted, including alcohol and cigarettes. Table 2 presents these results in rank order, beginning with those specialties that reported lifetime use of the fewest number of substances (i.e., family/general practice residents). Little difference was observed in past month and past year means across the specialties except for emergency medicine and psychiatry residents, who tended to use more substances than residents in other specialties.

Are Residents in Some Specialties More Likely to Be Daily Users?

A single episode of use does not indicate a serious pattern of drug use. Daily use, defined as use of a substance 20 or more times in the past month, provided a measure of frequent use. Daily use of any substance was relatively rare for this population. Of the 1,754 respondents, only 85 (5%) were daily users of alcohol, only 65 (4%) smoked half a pack or more of cigarettes each day, only five (0.3%) used marijuana daily, and only one (0.1%) was a daily amphetamine user. There were no daily users of other substances.

Sufficient numbers of daily users for specialty comparisons existed only for alcohol and cigarette use. Psychiatry residents had the highest prevalence (9.1%) of daily cigarette use (half a pack or greater), with 3.7% of all residents reporting daily use. Psychiatry residents also had the second highest prevalence of daily alcohol use (9.1%). Pathology residents had the highest prevalence of daily alcohol use (11.8% compared to a mean of 4.9% for all residents) but were least likely to be daily cigarette smokers. Obstetricians showed a reverse pattern, with the second highest percentage (6.4%) of daily cigarette smokers and the lowest percentage (1.9%) of daily alcohol users.

The five daily marijuana users were distributed among five different specialties. Although no subjects reported daily use of cocaine, one reported cocaine use six to nine times during the past month, and five reported using cocaine three to five times in the past month. These cocaine users were distributed among five specialties. Only four respondents reported benzodiazepine use as often as six to 19 times in the past month, and they were equally divided between family/general practice and psychiatry.

Less than 0.2% reported dependence on any substance in the past year, except cigarettes (2.3%). Of these, psychiatry (5.6%) and obstetrics/gynecology (5.5%) had the highest rates of cigarette dependence.

FIGURE 1. Use of Cigarettes and Illicit Substances in the Past Year by 1,754 Resident Physicians, by Specialty

FIGURE 2. Unsupervised Use of Prescription Substances in the Past Year by 1,754 Resident Physicians, by Specialty

These two specialties also had the highest rates of daily cigarette use.

Are Residents in Some Specialties More Likely to Use Controlled Substances Under the Supervision of Another Physician?

Residents were asked if they had taken prescription substances (amphetamines, barbiturates, opiates, or benzodiazepines) under a physician's supervision within the past year. The rates of physician-supervised substance use were very low. None of the respondents reported being prescribed amphetamines in the past year, only 0.6% (N=10) were prescribed barbiturates, 1.3% (N=22) were prescribed opiates, and 1.7% (N=29) were prescribed benzodiazepines. No differences among specialties were observed in the supervised use of any of these controlled substances.

Respondents were also asked if they had used these same four substance types in the past year for self-

TABLE 2. Number of Psychoactive Substances Used by 1,754 Resident Physicians, by Specialty

Specialty	Number of Substances Used					
	Past Month		Past Year		Ever	
	Mean	SD	Mean	SD	Mean	SD

Psychiatry	1.4	0.9	1.8	1.1	4.4	2.3

treatment. No specialty use pattern was observed for amphetamines and barbiturates, but residents in family/general practice and psychiatry had a tendency toward self-treatment with benzodiazepines and opiates.

Can the Differences in Observed Substance Use Rates Be Better Explained by Demographic Characteristics Than by Specialty Status Alone?

Specialties did not vary by age but did vary by gender and marital status (table 3). To evaluate whether specialty was associated with drug use independent of demographic characteristics, specialties were stratified by gender and marital status. Past year benzodiazepine and marijuana use was chosen in order to have sufficient numbers of drug users to make meaningful comparisons. Neither gender nor marital status explained differences in use among specialties. For example, both male and female psychiatry residents had the highest rates of benzodiazepine and marijuana use among the specialties. Similarly, marital status had no effect on the rates of benzodiazepine and marijuana use among psychiatry residents.

METHODOLOGICAL ISSUES

This survey has a larger and more representative sample than any previous effort to describe substance use among resident physicians in the United States. However, the limitations in sample size for some specialties in this analysis are recognized. For this reason, 95% confidence intervals are included in table 1. The overall response rate of 60% after three mailings may have been affected by the sensitive nature of the questions, the busy schedules, and high geographical mobility of the subjects. Nevertheless, the response rate compares favorably to that of other drug use surveys of resident physicians (7, 9, 10, 17).

Research on the reliability of substance use surveys suggests that self-reported information on drug use can be reliable when anonymity of subjects is assured (18).

In this study respondents were assured of our inability to link them to their responses. Yet although the anonymous mailed questionnaire generated reliable data on drug use, it did not measure substance abuse and dependence. Prevalence rates represented the percentage of users in the studied population and not diagnosed cases of substance abuse or dependence. Methods for diagnosing substance abuse and dependence are much more expensive and generally require direct interviewer contact and loss of anonymity.

The limited number of specialty choices available to respondents resulted in a group of 72 subjects in the "other/undecided" category. Although findings did reveal some interesting substance use trends among these respondents, their heterogeneity prevented more detailed specialty comparisons. Future questionnaires could be designed to identify respondents in smaller specialties and subspecialties.

DISCUSSION

The resident physicians in this survey were not heavy drug users and did not report dependence on substances other than cigarettes. When compared with a national sample of their U.S. age peers surveyed the same year, they reported lower rates of use for all drugs except alcohol and benzodiazepines (12). We conclude, however, that some specialties were indeed more likely to use specific classes of drugs, to use a greater number of drug classes, and to be daily users of alcohol and/or cigarettes. Specialties did not differ in the legitimate use of controlled substances under the supervision of another physician. Finally, the observed differences in substance use rates were not explained by demographic characteristics.

These findings are consistent with several studies that show psychiatrists at greater risk for substance use than other specialties (1, 2, 8-10). This survey confirms Maddux et al.'s finding that psychiatry residents are more likely to use benzodiazepines (9). Psychiatry residents also reported higher overall rates of marijuana and amphetamine use than residents in other specialties, used more substance types, and were more likely to be daily cigarette smokers and dependent on cigarettes in the past year. Although psychiatry residents were more likely to have tried cocaine, LSD, and other psychedelics in their lifetime, they were not more likely than residents in other specialties to be current users of these substances.

The higher rates of benzodiazepine use by psychiatry residents are of interest, since this class of dependence-producing substances occupies a pivotal position in the specialty's therapeutic armamentarium. Although no data were collected on prescribing practices in this survey, Koch and Knapp (19) reported that psychiatrists were more likely than physicians in 12 other specialties to prescribe controlled drugs. Koch and Knapp did not describe the specific types of substances prescribed by different specialties, but psychiatrists do see patient populations for whom benzodiazepines, and to a lesser

^aPercents were based on the number of respondents for that item.

extent barbiturates and amphetamines, can be legitimately prescribed.

A drug availability or exposure hypothesis might therefore explain higher rates of use for the types of substances prescribed by this specialty, but it would not explain higher rates of use of alcohol, marijuana, and cigarettes. Other possible explanations for higher rates of substance use among psychiatry residents include self-medication for higher levels of perceived anxiety or stress by members of this specialty (20), greater likelihood of prolonged and close exposure to drug-abusing patients, and more extensive training in the use of medications to improve mood and psychological state.

This survey also supports previous studies that identified a higher risk of substance use among emergency medicine practitioners (2, 4, 6). Emergency medicine residents had the highest proportion of cocaine users in the past year and past month and generally higher rates of use of cigarettes, marijuana, benzodiazepines, and psychedelic substances. They resembled psychiatry residents in having more multiple users, but they did not have high rates of daily use. Physicians in this specialty often have significant periods of leisure following long hours of intense, highly stressful duty. They have frequent contact with drug users and have access to most dependence-producing medications in their work. Additional study will be necessary, however, to clarify this specialty-drug use association.

Anesthesiology residents did not report the heavy substance use described in the literature (21). Anesthesiologists were overrepresented among Canadian resident physician drug users (10), impaired physicians treated by Talbott et al. (4), and physicians in the California impaired physicians program (6). Anesthesiologists also have high rates of drug-related deaths (22, 23). Higher rates of use have been attributed to the anesthesiologist's daily handling of dependence-producing substances.

The finding of lower than expected substance use by anesthesiology residents, if substantiated by further data, gives some reason for optimism. It suggests that aggressive preventive efforts in a specialty with previously reported high rates of impairment and identifiable risk factors can lead to a reduction in substance

use. These efforts include preventive education, new procedures to improve accountability for administered narcotics, and formal policies for handling cases of substance abuse (24, 25). Other specialty societies with high rates of substance use might learn from the experience of anesthesiology, but it is not known if risk factors in other specialties, beyond that of drug availability, could be so readily identified and addressed.

Specialties with lower rates of substance use include pathology, pediatrics, and surgery. Pathology residents used fewer types of substances in the past year and past month, were least likely to smoke cigarettes in the past year and month, and were least likely to ever use cocaine. This raises the question of potential preventive influences of residency training in a specialty that dramatically confronts a young physician with the end stages of substance use morbidity. Pathologists are also among the least exposed to one of the hypothesized risk factors in physician drug use—that is, their clinical responsibilities do not require them to prescribe dependence-producing substances.

Pediatricians in this sample were least likely to use alcohol and were among the least likely to use benzodiazepines. Although there is no ready explanation for their lower rates of use, pediatricians tend not to prescribe the types of substances associated with physician impairment. Surgery residents also had consistently lower rates of substance use, especially for LSD, other psychedelics, and benzodiazepines. Their only high drug use ranking was for alcohol use in the past month. The specialties of family/general practice, internal medicine, and obstetrics/gynecology were not among the highest or lowest use groups for most substances.

Despite striking findings on specialty drug use patterns, the data presented in this report do not answer a number of important questions relevant to specialty substance use. For example, are the differences in drug use patterns observed here attributable to the different types of people who enter high- and low-risk specialties or to differences in specialty training and practice environments? What is the influence of variation in drug availability and prescribing practices, specialty-specific stressors, and different levels of supervision and support? Do the substance use patterns of

resident physicians have a direct relationship to more serious forms of drug dependence that appear later in their careers?

Treatment programs and state disciplinary boards have data on sizable samples of impaired physicians that could help clarify some of these issues, but many of these questions can only be resolved in studies with focused questions and samples of adequate size. We are addressing some of these issues in a larger survey of U.S. physician substance use that considers specialty sample size, career stage, and drug availability in the study design.

Second-Trimester Markers of Fetal Size in Schizophrenia: A Study of Monozygotic Twins

H. Stefan Bracha, M.D., E. Fuller Torrey, M.D., Irving I. Gottesman, Ph.D.,
Llewellyn B. Bigelow, M.D., and Christopher Cuniff, M.D.

***Objective:** Since the second prenatal trimester is the critical period of massive neural cell migration to the cortex, and fingertip dermal cells migrate to form ridges during this same period, the authors sought to determine whether there are differences in fingertip ridge count in pairs of monozygotic twins discordant for schizophrenia, possibly indicating that a prenatal anatomical insult affected the twins differently. **Method:** The fingertip dermal ridges of 30 pairs of monozygotic twins (23 pairs in which the twins were discordant for schizophrenia and seven pairs in which both twins were normal) were counted by two persons trained in anthropometric research. Intrapair differences in the counts were then measured, and the differences among the pairs of normal twins were compared with the differences among the pairs discordant for schizophrenia. **Results:** The twins discordant for schizophrenia had significantly greater absolute intrapair differences in total finger ridge count and significantly greater percent intrapair differences than the normal twins; i.e., their fingerprints were significantly less "twin-like." **Conclusions:** The study suggests that various second-trimester prenatal disturbances in the epigenesis of one twin in a pair discordant for schizophrenia may be related to the fact that only one of the twins expresses his or her genetic predisposition toward schizophrenia. This is consistent with a "two-strike" etiology of schizophrenia: a genetic diathesis plus a second-trimester environmental stressor.*

(Am J Psychiatry 1992; 149:1355-1361)

The task ahead is to discover how genes and environment interact to produce schizophrenia. Of course, it is much easier to talk about such epigenetic interactions than to design experiments that will elucidate them! (1, p. xii)

This twin study was designed to elucidate epigenetic interactions of genes and environment in producing schizophrenia. Genes that predispose to psychosis may be expressed by making individuals

more vulnerable to the disruptive effects of various commonplace prenatal insults. Recent studies indicate that many prenatal insults do not always affect both monozygotic twins to the same extent. We used the monozygotic-twin research strategy to estimate differences in environmental interference that disrupts fetal development in the second prenatal trimester. The second trimester is the critical period of massive neural cell migration to the cortex. Fingertip dermal cells also migrate to form ridges during this trimester. Differences between monozygotic twins in the anatomical dermal feature called "finger ridge count" may serve as "fossil" ("chrono-marker") evidence for any of a variety of factors that might affect one fetus differentially during the second prenatal trimester.

The study of discordant monozygotic twins is one of the most powerful methods used for sorting out the relative roles of genetic and environmental variance in medicine (2-7). For example, recent studies suggest that the monozygotic twin with chronic schizophrenia has larger ventricles and smaller temporal lobes than the nonaffected twin (4). Such important findings in schizophrenia may localize the insult in space, but not in time; that is, the brain cell loss could have occurred at any time prior to the examination.

Presented in part at the annual meeting of the American College of Neuropsychopharmacology, San Juan, Puerto Rico, Dec. 10-15, 1990. Received July 27, 1990; revision received Jan. 28, 1992; accepted Feb. 24, 1992. From the Child and Adolescent Division, Department of Psychiatry and Behavioral Sciences, University of Arkansas for Medical Sciences, Little Rock; the Psychiatry Service, North Little Rock VA Medical Center; Arkansas Children's Hospital, Little Rock; the Twin Studies Unit, NIMH, Washington, D.C.; and the University of Virginia, Charlottesville. The authors thank Robert Walls, Ph.D., and Roscoe Dykman, Ph.D., for statistical consultation, Beata Przybyla, Ph.D., for expertise in quantitative dermatoglyphics, and David A. Webb and Saeid Khan-sarina, M.D., for technical assistance.

Given the lack of confirmation that a single major gene causes schizophrenia (2), there has been renewed interest in studies of monozygotic twins to examine the diathesis-stressor, multifactorial etiology of schizophrenia (2, 3). Unaffected twins in monozygotic twin pairs discordant for schizophrenia (one healthy twin and one schizophrenic twin) are considered to be examples of unexpressed genotypes of schizophrenia, presumably because they did not encounter a putative environmental "stressor" or "releaser" (3). The nature of the stressors or releasers has long been debated (2).

Minor facial physical anomalies (8) and minor physical asymmetries of parallel structures (9–11) are anthropometric markers found in schizophrenia that are known to reflect prenatal insult. However, the pediatric literature associates minor physical anomalies with first-trimester insults. Unlike minor physical anomalies, the embryology and genetics of the anthropometric feature known as total finger ridge count (see Method section for definition) have been thoroughly studied (12, 13). There is no such thing as an "abnormal" ridge count. However, two long-held notions—that fingertip ridge count is one of the most stable and reliable anthropometric measures and that monozygotic twins have nearly identical fingertip ridge counts—have been confirmed in recent studies. These studies show that 1) the ridge counts of monozygotic twins have an intrapair intraclass correlation of 0.96 (14)—in other words, the expected intrapair difference in ridge count between monozygotic twins approaches zero—and 2) tests of interrater reliability in ridge counting for the same individual show a correlation of 0.99 (14). Fingertip ridge counts have correlations of 0.05 and 0.49 in randomly selected individuals and first-degree relatives, respectively (5, 15, 16).

Because healthy monozygotic twins have nearly identical fingerprint ridge counts (5, 14–16), the expected intrapair difference in ridge count between two monozygotic twins free of prenatal injury approaches zero. We used this fact and a study group of monozygotic twins discordant for schizophrenia to try to localize, in time, insults to the fetal brain that may contribute to the expression of schizophrenia-related genes.

Ridge count (unlike more conventional neurodevelopmental markers such as brain ventricle size) is a permanent anatomical feature that is not permanently disrupted by postnatal insults to the subject's brain or body, such as use of psychotropic medication, drug or alcohol abuse, aging, dehydration, or trauma (12, 17–19). For this reason, ridge count remains the mainstay of person-identification techniques (19).

Ridge count has long been replaced by newer methods of determining zygosity, mainly because it is disrupted by various intrauterine insults (12, 13). The only environmental conditions that can change ridge count are intrauterine ones (12, 13, 18, 20–22). Ridge count has therefore been extensively used in recent research on prenatal injury (11, 21–23) and serves as a useful marker of deleterious intrauterine experience (18, 24). Cummins and Midlo (12) were the first to point out

that "dermatoglyphics . . . are significant indicators of conditions existing several months prior to the birth of an individual Dermatoglyphics reflect the existence of differences dating from the fetal period. This freedom from the effects of later environmental influences is shared by few other traits which are accessible to investigation . . . [and] dermatoglyphics may aid in some investigations which call for reconstruction of events in the intrauterine history of an individual" (pp. 185–186).

Recent data, collected with a comprehensive National Institute of Mental Health (NIMH) prenatal history questionnaire for mothers of monozygotic twins, suggest that differences in total finger ridge count between normal monozygotic twins correlate most strongly with second-trimester deleterious events. We administered a questionnaire about deleterious events during pregnancy to a group of 30 mothers of monozygotic twins from a twin registry. We also measured the absolute intrapair differences in fingertip ridge count for each twin pair. The subscale measuring deleterious events that occurred during the second trimester in utero was the best predictor of increased intrapair differences in total finger ridge count and accounted for 36% of the variance. The next best predictor accounted for less than 2% of the variance (unpublished paper of Bracha et al.). A review of the embryological literature also indicated to us that total finger ridge count may be a specific marker for environmental insult in the second trimester of pregnancy (12, 13, 18, 21, 23, 24). Fingertip dermal cells migrate to form ridges (fingerprints) during the second prenatal trimester (13, 18). Abnormalities in fingertip ridge count have been reported in subjects with developmental brain disorders in which second-trimester systemic insults to the fetus are hypothesized to interact with genetic vulnerability (13), including the following: developmental reading disorder (22), some cases of mental retardation (23), fetal alcohol syndrome (25), and in utero viral infections (e.g., rubella and cytomegalovirus) (13, 26–28).

Studies of prenatal rubella infections clearly indicate that although the effect of the virus is paramount, the virus may be necessary *but not sufficient* to produce the clinical entity. Some genotypes cause individuals to be more sensitive than others to the neuropathogenic effects of prenatal rubella (27). Similarly, genes that predispose to schizophrenia may act by merely making individuals more vulnerable to the disruptive effects of various commonplace prenatal insults (3).

There have been several previous ridge count studies of schizophrenia. Most of them were performed before the effects of prenatal insults (e.g., rubella) were discovered and were patterned after studies of trisomy 21 (29). These studies resulted in inconclusive findings (unpublished review paper by Przybyla and Bracha). Three common flaws in the studies were 1) failure to control for genotype, 2) failure to take into account the fact that there is no such thing as an abnormal ridge count, and 3) failure to realize that since ridge count directly correlates with second-trimester fetal size (12,

13, 30), one twin's deviations from the measurements of his or her normal monozygotic twin need not always be in the same direction to be informative. Specifically, in a set of monozygotic twins, one twin's lower ridge count than that of the nonaffected twin is associated with insults which retard the physical growth of the affected fetus during the second trimester (30). Conversely, an affected monozygotic twin's having a higher ridge count than that of his or her nonaffected twin is associated with second-trimester insults that produce generalized fetal edema in the affected twin and thus make the fetal fingertip volar pads larger (13). A discrepancy in ridge count in either direction in monozygotic twins can thus be viewed as a second-trimester fetal size marker (i.e., a chrono-marker) and is the "fossilized" result of random minor, mostly unrecognized insults that caused either growth retardation or edema in the affected twin during that trimester (12, 13).

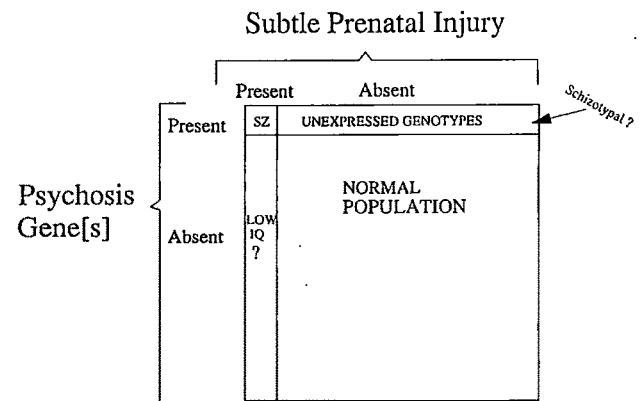

It has recently become clear that many prenatal insults, especially ischemias, frequently do not affect both monozygotic twins to the same extent (18, 31-33). In this study we fully controlled for the genetic contribution to fingertip dermal features by comparing the intrapair differences in fingertip ridge count in two groups of monozygotic twin pairs: twins discordant for schizophrenia and nonpsychotic twins. Slater's well-known sample of monozygotic twins discordant for schizophrenia (5) was far too small to allow this intrapair kind of analysis. We hypothesized that the intrapair differences in ridge count of monozygotic twins discordant for schizophrenia would be larger than those of nonpsychotic monozygotic twins.

METHOD

The study subjects were 23 pairs of twins (46 individuals) from the United States and Canada recruited over a 7-year period (1984-1990) by the Twin Studies Unit at NIMH as part of a large multidimensional study of twins discordant for schizophrenia (4). This group has been exhaustively studied and described in part elsewhere (4, 7). All of the twin pairs were monozygotic, as determined by physical similarities (by I.I.G.) and as confirmed by 19 RBC antigens.

Each individual was interviewed by two senior NIMH research neuropsychiatrists (L.B.B. and E.F.T.) with the complete Structured Clinical Interview for DSM-III-R, Patient Version (SCID-P), parts I and II (34). The SCID videotapes were also examined by a senior clinical psychologist-geneticist (I.G.G.). All psychiatric diagnoses were made according to DSM-III-R criteria. Nine of the 23 pairs were female and 14 were male. Their mean age was 32.5 years (range=19-46) at the time of the analysis. The mean length of discordance was 11.2 years (range=4-24). Discordant pairs with fewer than 4 years of discordance were excluded a priori from the analysis. Belmaker et al. (6) have shown low rates of conversion to concordance beyond the 4-year period. On the basis of risk rates and data from the studies of monozygotic

FIGURE 1. The "Two-Strike" Hypothesis of the Etiology of Schizophrenia (SZ)

twins by Pollin and associates at NIMH (6), we estimate that only a few of the 23 discordant pairs are likely to become concordant.

Genes that predispose to schizophrenia may act by making individuals more vulnerable to the brain-disrupting effects of commonplace prenatal insults. Consequently, nonschizophrenic genotypes who suffer a second-trimester insult may manifest ridge count anomalies without manifesting schizophrenia. Therefore, by design, the study group of twins and a comparison group of normal twins should not be matched for prenatal insults or family history (4, 7). Also, by design, the only two requirements for inclusion in the comparison group in this study were no diagnosis of psychotic illness and no known history of prenatal insults according to information from the 39-item NIMH prenatal history questionnaire.

As we have mentioned, the expected intrapair difference in ridge count for monozygotic twins free of prenatal injury approaches zero (5, 14, 15, 35). We obtained the fingerprints of a comparison group of nonschizophrenic subjects consisting of seven pairs of adult monozygotic twins (14 individuals). Three of the seven pairs were male and four were female. Six of the nonschizophrenic pairs had been extensively studied and described elsewhere (4, 7). One subject in each of two of these pairs met the criteria for a single episode of major depression in full remission (DSM-III-R diagnosis 296.26) when administered the SCID. Four of the pairs were found to have no mental illness (DSM-III-R V code 71.09) according to the SCID (nonpatient version). The seventh pair of nonschizophrenic monozygotic twins (72-year-old sisters) was recruited mainly because of its high genetic loading for schizophrenia (one younger sister with chronic schizophrenia and one aunt with an early onset of psychosis). This caused the pair to be especially valuable for the study because, according to the "two-strike" hypothesis of the etiology of schizophrenia (figure 1), normal monozygotic twins who are genetically at risk but do not phenotypically express schizophrenia should not have an elevated intrapair difference in total finger ridge count. This rea-

FIGURE 2. Method Used for Total Finger Ridge Count^a

^aPrints are from one pair of monozygotic twins discordant for schizophrenia.

soning notwithstanding, statistical analyses demonstrated no differences between the pairs of twins discordant for schizophrenia and the normal comparison pairs in the number of prenatal insults as recorded by the NIMH prenatal history questionnaire (unpublished paper of Taylor et al.).

Using standard inking techniques, we obtained prints from each finger on both hands for all subjects (Faurot Crime Detection Equipment, Elmsford, N.Y.). The total finger ridge count analyzed in this article was from the first counting for every subject. Figure 2 shows the method used. All ridges along a straight line connecting the triradial point to the closest point of the core were counted. Ridges containing the point of the core and the triradial point were excluded. The sum of the ridge counts for all 10 fingers yielded the standard total finger ridge count for each person (9, 17, 19). The counting was done by a research assistant (S.K.) who was trained in the standard technique of dermatoglyphic ridge counting (13, 19) and who was unaware of the twins' diagnoses and pair membership.

To establish the reliability of the ridge count data, ridges of all the twins studied were also independently counted by a trained medical geneticist (B.P.). After this second counting, an intraclass correlation coefficient was computed. The resulting correlation for the two raters was 0.98, indicating a high degree of reliability of the ridge count data.

By design, family history was not an exclusion criterion for the normal comparison group, nor was prenatal insult an exclusion criterion for the twins discordant for schizophrenia. Data on twins are unique because an individual can serve as his or her twin's "built-in" comparison subject. In other words, studies of monozygotic twins allow a powerful and unique design in which the unaffected member of each pair can be viewed as the affected member before he or she was affected (3, 4, 7). Our data were accordingly analyzed in two ways.

First, the intrapair difference in total finger ridge count was obtained for each pair, resulting in 23 difference scores for the twins discordant for schizophrenia and seven for the comparison group. Because any discordance in total finger ridge count is important regardless of direction (plus or minus), the absolute value of

the difference was used. A mean of these absolute intrapair differences was obtained for each group. Because of the small size of the comparison group, the unequal group sizes, and the lack of assumption of normality for the data being analyzed, a nonparametric statistic (the Wilcoxon two-sample rank sum test) was computed to test whether the mean differences in total ridge counts for the two groups were significantly different.

Second, we analyzed percent intrapair differences, because in pairs with genetically low total finger ridge counts, even a small absolute discrepancy translates into a relatively high percent difference. For the group of twins discordant for schizophrenia, the unaffected twin's total finger ridge count was used as the denominator, and the resulting value was expressed as a percentage (affected twin's total finger ridge count minus unaffected twin's total finger ridge count, divided by unaffected twin's total finger ridge count, multiplied by 100). For the seven pairs of normal comparison twins, there was no obvious reason to place the total finger ridge count of one of the twins in the denominator, so the smaller total count of the two was used (one twin's total finger ridge count minus the other twin's total finger ridge count, divided by the smaller of the two counts, multiplied by 100). This conservative approach maximized the size of the difference in the comparison group, and this maximization was in the direction of the null hypothesis. Absolute values were also used here. A mean of the percent intrapair differences in total finger ridge count was calculated for each group, and again the nonparametric Wilcoxon two-sample rank sum test was used so as to avoid assumptions about the normality of the distribution.

There was one outlier pair at more than three standard deviations above the mean in the group of twins discordant for schizophrenia, and the Wilcoxon two-sample rank sum statistic was computed for both analyses to test for significant differences with this pair removed. We also tested for any effect of gender by using a Wilcoxon two-sample rank sum test on absolute intrapair differences and percent intrapair differences in both the group of twins discordant for schizophrenia and the normal comparison group, with gender as the grouping factor. Since our hypothesis was clearly in one direction, we used the one-tailed probability value for all analyses, and alpha was set at $p < 0.05$.

RESULTS

Table 1 displays total finger ridge counts, absolute intrapair differences, and percent intrapair differences for the twins discordant for schizophrenia, and table 2 shows the same data for the normal comparison twins. The results of the analyses for mean percent intrapair differences are shown in figure 3.

The mean absolute intrapair difference in total finger ridge count for the group of twins discordant for schizophrenia (12.2, $SD=9.7$) and that for the comparison group (4.4, $SD=5.2$) were significantly different

($z=-2.4$, $p=0.008$). This finding was in the hypothesized direction, i.e., a greater difference in the discordant group than in the comparison group.

The mean percent intrapair difference in total finger ridge count for the group of twins discordant for schizophrenia (10.9, SD=11.2) and that for the comparison group (2.8, SD=2.9) were also significantly different ($z=-2.5$, $p=0.006$). This finding was also in the hypothesized direction.

No significant effect of gender was found in either of the two groups. The mean percent intrapair difference in total finger ridge count of the twins discordant for schizophrenia was 10.08 for the female pairs and 11.14 for the male pairs.

Also, when we recomputed the analyses of mean absolute intrapair differences and mean percent intrapair differences in ridge count between the two groups, with the outlier pair removed from the group discordant for schizophrenia (N=22), the differences between groups remained significant.

DISCUSSION

To our knowledge, this is the first report of a study in monozygotic twins of a quantitative prenatal insult marker in an adult medical condition. The monozygotic twins discordant for schizophrenia had a higher intrapair discrepancy in fingertip ridge count than the nor-

mal twin pairs; i.e., their fingerprints were significantly less "twin-like." This finding extends our previous quantitative clinical study in which we found more minor physical anomalies in the hands of the probands in the same monozygotic twin sample (36).

Ridge count, like height, is under polygenic control (17). Ridge count is increased, for example, in patients with monosomy of the X chromosome (Turner's syndrome), and it is decreased in Klinefelter's syndrome (47,XXY). It is also decreased with the deletion of the short arm of chromosome 5. The effect of these genetic aberrations on ridge count is presently thought to be indirect and mediated through their effect on fetal size in relation to gestational age (30). A postfertilization somatic mutation affecting second-trimester ectodermal cell migration in the affected twin or a split at the blastocyst stage as suggested by Roberts (37) are two conceivable, though unlikely, explanations for the ana-

tomical differences in ridge count and brain structure between monozygotic twins discordant for schizophrenia. Since discordance for schizophrenia in monozygotic twins is about 50%, such an explanation would assume an implausible postfertilization mutation rate of 50%. The results of the present study are more consistent with a diathesis-stressor, two-strike etiology of schizophrenia (2, 3, 10, 38–40), with differences in ridge count being a marker of the intrauterine insults that have provided the second strike. A similar two-hit etiology for some cancers has been proposed by Knudson (40).

This study suggests that the monozygotic twins discordant for schizophrenia were significantly more discordant in size than the healthy monozygotic twins during the second trimester in utero. Second-trimester conditions that could result in a brain injury coupled with a prenatal size discrepancy (and thus a ridge count discrepancy) between monozygotic twins include the following: anemia, anoxia, ischemia, maternal alcohol or drug abuse, maternal toxin exposure, and twin transfusion syndrome. All of these can produce smaller fetal size and therefore a lower total finger ridge count. In contrast, prenatal infections produce generalized fetal edema (including fingertip edema) and thus a higher total finger ridge count (24, 26). Any of these postfertilization prenatal insults, regardless of the direction in which they affect total finger ridge count, could increase the expression of genetic vulnerability to a psychotic disorder by interfering with cell migration from the germinal matrix to the cortex (41).

The literature clearly indicates that the etiology of schizophrenia in twins is not different from the etiology of schizophrenia in singletons (3). Therefore, the findings of this study should be generalizable to all patients with schizophrenia. Obviously, only a monozygotic-twin research strategy can properly control for genotype and therefore allow us to measure differences in this marker of second-trimester environmental interference with intrauterine dermal cell migration. It has been recently suggested, on the basis of epidemiological data, that some patients with the schizophrenic syndrome have been exposed to infection during the second trimester (42). However, there is a growing consensus that neither genetics nor perinatal complications alone are the sole cause of schizophrenia, even in subgroups of schizophrenic persons (38). The results of this study are consistent with the multifactorial diathesis-stressor, two-strike model of the etiology of schizophrenia (2, 3, 10, 38, 39, 41).

We demonstrated fingertip ridge count evidence for second-trimester insult in about one-third of the monozygotic twin pairs who were discordant for schizophrenia. Not all of the discordant twin pairs displayed this anatomical marker of second-trimester insult. This heterogeneity in schizophrenia is not surprising, because the expression of a psychosis-related gene or genes can probably be increased also by postnatal insults or by prenatal insults that would not alter fetal size (and thus ridge count). Nevertheless, ridge count

may be a more sensitive and more specific marker of second-trimester size in monozygotic twins than either minor physical anomalies or even birth weight. A twin whose size was retarded during the second trimester can easily "catch up" to the unaffected twin in birth weight during the third trimester, because 75% of birth weight is gained in the third trimester (18, 31, 43). This twin study provides direct anatomical evidence that phenotypic schizophrenia in genetically exposed individuals may be associated with various (probably heterogeneous) insults that also affect size in relation to gestational age during the second prenatal trimester.

Ridge count may serve as a moderately sensitive but most specific marker of second-trimester fetal size in future studies of monozygotic twins. Fingertip ridge counts should be obtained and analyzed as a dependent variable in all future studies of psychiatric disorders in monozygotic twins. If replicated, this twin study may also have public health implications regarding the importance of second-trimester prenatal care in preventing the expression of severe adult, adolescent, and child behavioral disorders.

Smooth Pursuit Ocular Motor Dysfunction in Schizophrenia: Evidence for a Major Gene

William M. Grove, Ph.D., Brett A. Clementz, Ph.D., William G. Iacono, Ph.D.,
and Joanna Katsanis, M.A.

Objective: Evidence suggests that poor eye tracking relates to genetically transmitted vulnerability for schizophrenia. The authors tested competing models for the genetic transmission of poor eye tracking in a search for major gene effects. **Method:** Samples from three studies (conducted in Minneapolis, New York, and Vancouver, B.C.) were pooled. Probands (N=92) were diagnosed as schizophrenic by DSM-III criteria. Of the comparison subjects (N=171), Vancouver patients were an epidemiologic first-episode group; at other sites unselected admitted patients were studied. First-degree relatives (N=146) of 65 probands were also studied. Eye tracking was measured while subjects followed a horizontally moving, sinusoidally driven (0.4 Hz) spot of light on a screen. Performance was quantified by root mean square error. Data analysis was by complex segregation analysis (Bonney's class D regressive models). **Results:** A single major gene is needed to account for poor eye tracking in schizophrenic patients and their relatives. This gene alone can explain about two-thirds of the variance in eye tracking performance. A single gene alone (regardless of dominance) will, however, not account for the data; polygenic factors are also required. **Conclusions:** Results support postulation of a single gene for ocular motor dysfunction, which may be a risk factor for schizophrenia. Eye tracking may be useful as a gene carrier test in genetic studies of schizophrenia.

(Am J Psychiatry 1992; 149:1362-1368)

Well-conducted family, twin, and adoption studies support the role of genetics in the transmission of schizophrenia (1-3), although risks to relatives vary among studies (2, 4). The literature justifies the conclusion that a single gene alone cannot account for transmission of schizophrenia (5, 6). It is nonetheless possible that a single gene contributes strongly to risk. A chromosome 5 translocation family (7) and an English-Icelandic linkage study (8) suggest a role for a gene on chromosome 5. However, replication attempts have failed (9, 10).

It may be the case that a major gene, in addition to numerous other genes that are individually not very influential, accounts for risk. Gottesman and McGue (11) recently demonstrated that a moderately common allele of relatively modest effect on risk (10% risk for schizo-

phrenia), together with polygenic factors, can account for the data (12). Two, three, or more genes can also be used to account for the empiric risks (13).

One reason it may be hard to find a gene for schizophrenia is low penetrance (probability of manifesting schizophrenia given a susceptible genotype). For example, if a dominant gene accounted for the transmission of schizophrenia, half of parents and siblings would be carriers. Since roughly 6%-10% of these develop schizophrenia in pre-DSM-III studies (2) versus less than 6% under DSM-III (4), risk to carriers would lie in the range of 12%-20%. This would make it hard to decide whether a nonschizophrenic relative was a gene carrier (14). Prospects of finding a major gene could improve if one had a good carrier test. With suitable carrier tests, and given a strong effect of a putative gene on schizophrenia risk, one could sort relatives by risk category.

Perhaps the currently most promising way to detect putative gene carriers for schizophrenia is eye tracking dysfunction (15, 16). This abnormality has a low base rate (4%-5%) in normal subjects and their relatives (17), is temporally stable (18), and is found in a specific subset of schizophrenic patients and their relatives (17, 19). Eye tracking dysfunction also correlates with schizotypal personality features in relatives of schizophrenic patients (20, 21).

Recent research has demonstrated that measures of eye tracking dysfunction are bimodally distributed in patients with schizophrenia and in their relatives (17, 22). Further, Iacono et al. (23) studied eye movements in Bassett et al.'s (7) trisomy 5 family and showed that the two schizophrenic, partially trisomic members had eye tracking dysfunction while the three nonschizophrenic, nontrisomic members did not. This suggested an association between eye tracking dysfunction and a genetic abnormality conjecturally tied to schizophrenia.

Two published studies of the familial distribution of schizophrenia and smooth pursuit eye movement dysfunction by Matthysse, Holzman, and colleagues (24, 25) used a "Mendelian latent structure analysis" model, which presumes that the only genetic cause common to schizophrenia and eye tracking dysfunction (in schizophrenic patients' families) is a dominant gene. Neither of these studies tested for a major gene effect against models incorporating only polygenic factors, as needs to be done (26). Further, family and twin data show that a single gene cannot account for the transmission of schizophrenia (12, 13, 27). The data of Matthysse, Holzman, and colleagues, as presented, therefore, neither compel nor uniquely favor a single-gene hypothesis (27-29).

The Mendelian latent structure model makes predictions about familial resemblance for schizophrenia and/or eye tracking dysfunction. If a major gene affects risks for schizophrenia and ocular motor dysfunction, it follows that the gene affects the risk for each trait alone. Therefore, one can test the theory of Matthysse, Holzman, and colleagues by looking at ocular motor dysfunction alone.

In this report we improve on previous efforts to identify single-gene influences on schizophrenia in three ways. First, instead of examining diagnosed schizophrenia, we use a presumably simpler trait, ocular motor dysfunction, specifically related to schizophrenia risk. Second, unlike Matthysse, Holzman, and colleagues (24, 25), we use a quantitative indicator of ocular motor dysfunction rather than dichotomous ratings of eye tracking dysfunction. Maclean et al. (30) showed that using quantitative traits improves the power of genetic analyses. Third, we directly test whether single-gene models fit the data by using standard statistical tests.

METHOD

Subjects

Subjects came from three separate studies in Minneapolis (21), New York (22), and Vancouver, B.C. (17). Probands were recruited from consecutive hospital admissions (Minneapolis, New York) or patients with consecutively reported first onsets of psychosis in a community network (hospitals, clinics, private practitioners, and counseling bureaus in Vancouver). All met *DSM-III* criteria for schizophrenia on the basis of struc-

tured interview. Details of subject selection and diagnosis are given in the cited reports.

Lists of first-degree relatives were compiled from patients and informant relatives. Relatives over age 15 years who lived in specified areas around study centers (e.g., 250-mile radius in Minneapolis) were invited to participate. Informed consent was obtained. Relatives were evaluated by structured interview (Diagnostic Interview Schedule [31] in Vancouver; Structured Clinical Interview for *DSM-III* [32] for other sites) for *DSM-III* schizophrenia. At two sites (Minneapolis and New York) relatives were also evaluated for schizophrenia-related personality disorders (with the Schedule for Schizotypal Personalities [33]). Last, subjects' eye movements were studied. The reader should note that our sampling scheme did not select for or against families that had multiple individuals with schizophrenia.

Community comparison subjects were obtained in Minneapolis and Vancouver. Recruitment involved screening family practice clinic visitors (Minneapolis) or by soliciting volunteers from community institutions (Young Men's Christian Association, union halls, family practices, and community colleges in Vancouver). Normal subjects were screened to exclude those with a personal or family history of psychotic disorders. These comparison subjects were used only for preliminary analyses (discussed later), not for genetic analyses.

Assessment of Eye Tracking Dysfunction

Details of stimulus presentation, response recording, and scoring are given elsewhere (17, 20, 21). Procedures were quite similar across sites. Briefly, a 0.4-Hz sinusoidally driven electronic target oscillated horizontally across a display screen. The target simulates the motion of a pendulum, but rather than transcribing an arc, its movement was restricted to one dimension. The stimulus traverse subtended 20° of visual arc. Eye tracking was recorded for 12 cycles of target motion. For two samples (Minneapolis and Vancouver), eye movements were recorded by electro-oculogram (EOG), while the New York study used infrared recording, digitized at 128 samples. These two types of recording yield measures that correlate very highly (18). Nevertheless, to ensure similarity across samples, all ocular motor recordings were filtered with a 30-Hz low-pass Blackman filter, preserving actual eye movements while reducing non-eye movement signals often found in the EOG.

Eye movements were scored by using a method developed by Iacono and Lykken (34). Each cycle of tracking and target motion was centered and normalized to eliminate amplitude differences between recordings of eye and target movements. When eye position lags behind the target (as it usually does), a phase difference occurs that can artifactually inflate eye tracking dysfunction scores. Therefore, target and eye channels were aligned so as to produce maximal cross-correlation between eye and target channels, minimizing this artifact. The squared difference between target and eye

position was then computed for each digitized sample, and for each cycle the square root of the mean of these squared differences was computed. The median of these cycle-by-cycle error measures constitutes the root-mean-square-error measure of eye tracking dysfunction analyzed in this report. Root mean square error thus provides an estimate of the degree to which a subject's eye movements resemble the motion of the target. All scoring was done in a manner that was blind to subject status and diagnosis.

The root-mean-square-error measure is a relatively global one, which indicates how bad eye tracking is without specifying how it is deficient. We chose it nonetheless because previous work has shown that it has desirable properties for behavior genetic analyses. It has high test-retest reliability (18), shows heritability in twins (34), is bimodally distributed in schizophrenic patients and in their relatives (17), and correlates highly with neuro-ophthalmologic measures of eye tracking dysfunction (e.g., oculomotor gain; reference 22).

Statistical Analyses

We compared samples before pooling them, using one-way analysis of variance. We also looked for age effects (by correlation) and sex effects (by *t* test) on eye tracking.

We then corrected for distributional skewness in root mean square error. Skewed variables cause problems because skewing can lead to simulation of major gene action (35). One remedy is to fit a skewness-reducing transformation along with the genetic model, but this often leads to trouble with parameter estimation. Therefore, we instead estimated a standardized Box-Cox power transform (36) to the comparison subjects' data. The Box-Cox method is flexible, allowing for sophisticated transformations. Logarithmic, square root, and other commonly used transformations occur as special cases of the Box-Cox transform. We estimated a Box-Cox transformation that essentially abolished skewness of root mean square error in our comparison group and applied this same transformation to our patients' families. Because almost all comparison subjects should be free of a relatively uncommon schizophrenia-proneness gene, it is unnecessary to consider major gene effects in this sample. Schizophrenic patients' family data were then transformed (using comparison subjects' transformation) before genetic analysis.

We carried out segregation analyses on transformed root mean square error in schizophrenic patients' families. Segregation analysis is a statistical methodology used to determine the mode of inheritance of a trait from family data. This procedure provides for the evaluation of goodness of fit between an inclusive model and a series of nested models in an effort to refute nested models of interest. Each model yields a likelihood statistic that indicates the probability of observing the data, given that the model is correct. The model fit is evaluated by calculating likelihood ratio χ^2 tests that indicate whether the nested model can be rejected.

That is, if the χ^2 test is significant, the data do not fit the nested model. A nonsignificant χ^2 indicates that the nested model cannot be rejected.

We used the Statistical Analysis for Genetic Epidemiology program REGC (version 3.0) (presented by R.C. Elston et al. at a conference in 1986), which computes Bonney's class D regressive models (37), making three main assumptions. First, there are just three familial influences on eye tracking dysfunction: major genotype, regression on parental eye tracking dysfunction values, and residual sibling resemblance in eye tracking. Second, the gene is a two-allele autosomal locus. Third, within major genotypes, siblings share a common regression on parental values and also share a common correlation with other siblings.

The following is a conceptual outline of the regressive segregation analysis models we used. The models are regression (i.e., prediction) models. They predict offspring genotype from parental genotype according to definite transmission rules, and they predict all the phenotypes (here, eye tracking scores) from the genotypes. These models incorporate both transmission due to major genes (i.e., following Mendel's laws of segregation) and transmission from parent to offspring such as occurs with polygenic inheritance (as when the average height of offspring lies midway between the parents' heights).

The models test the data for consistency with the following predictions, which are derived directly from genetic theory: 1) presence of parent-offspring (vertical) transmission, 2) tendency of eye tracking dysfunction scores to sort into distinct classes of dysfunction (i.e., multimodality or distribution admixture), 3) resemblance between parents and offspring, and among siblings, on eye tracking dysfunction scores that follow Mendelian ratios, and 4) resemblance between siblings over and above that found between parents and offspring. Passing the first test is, of course, required by any genetic model. The second tests whether "segregation" (tendency either to get or not get abnormal eye tracking, without in between cases) is occurring. The third test assesses whether any ostensible segregation is of a kind consistent with genetic, as opposed to, for example, environmental, transmission from parent to offspring. The fourth and final test tells us whether polygenic factors, in addition to a major gene, may be at work.

To capture all these phenomena requires a complex model. The models fit had the following parameters: q (frequency of genetic allele A causing eye tracking dysfunction); μ_{AA} , μ_{AB} , and μ_{BB} (transformed root mean square errors for major genotypes AA, AB, and BB); σ^2 (the within-genotype variance); ρ (this is the result of equating ρ_{PO} , the regression of offspring on parent, and ρ_{SS} , the residual sibling correlation—see later discussion); and τ_{AA} , τ_{AB} , and τ_{BB} (probability of transmitting an "allele" A for major genotypes). We assumed random mating with respect to eye tracking dysfunction, Hardy-Weinberg genotype proportions, no sex effect on root mean square error, and that mother-off-

TABLE 1. Characteristics of Schizophrenic Patients, First-Degree Relatives, and Normal Comparison Subjects in a Study of Genetics of Ocular Motor Dysfunction

Comparison subjects	171	91	33.6	14.6	141.4	107.7

spring, father-offspring, and sibling-sibling correlations were all equal. These assumptions appeared justified by our data (see later discussion). In contrast to other computer programs for segregation analysis, to test for no polygenic contribution to a trait, one fits a model that constrains correlations between biological relatives all to be zero.

Parameters were estimated by maximum likelihood, using direct search of the likelihood surface (starting from various initial parameter values), followed by Newton-Raphson iterations. Differences in log-likelihoods for various models yielded likelihood ratio χ^2 tests of model adequacy (see later discussion).

Since families were sampled by virtue of having a schizophrenic proband, an ascertainment correction needs to be made. We adopted a suggestion made by Elston (personal communication), namely, that one correct for ascertainment by conditioning on the proband's exact root mean square error score.

RESULTS

Subject Participation and Description

We recruited 92 schizophrenic patients; no family contained two probands. There were 146 participating first-degree relatives of 65 of these probands. We also studied 137 normal comparison subjects and 34 of their relatives. Sixty percent of all eligible relatives (i.e., over age 15 and living within specified geographical radii of our study centers) were studied in the laboratory. Table 1 shows descriptive statistics for subjects. Table 2 breaks down the numbers of families according to how many and what kind of relatives were tested. A large number of schizophrenic patients (N=27) had no evaluated relatives. These subjects were retained in data analyses because they help estimate the rate of eye tracking dysfunction in probands. This in turn improves our estimated frequency of the genetic allele influencing eye tracking dysfunction.

Among relatives, there were five schizophrenic patients (Weinberg short method morbid risk=4.3%, risk period=15-45 years) in five different families. Eye tracking data were available for four of these. For the two samples in which schizotypal personality was evaluated, 11.8% of relatives qualified for a definite *DSM-III* diagnosis. These values are close to those ob-

served by Baron et al. in a similar family study (38). Since analyses with and without the schizophrenic relatives yield similar conclusions, we kept schizophrenic relatives in the sample.

Preliminary Analyses

Our three samples of probands did not differ significantly on root mean square error ($F=0.94$, $df=2$, 86, $p<0.40$). However, relatives did differ ($F=14.23$, $df=3$, 142, $p<0.001$). This difference was entirely due to the Minneapolis sample relatives' lower root mean square errors. Three considerations led us, nevertheless, to pool all samples for this report. First, bimodality (confirmed by skewness-correcting admixture analysis) was found in both pooled New York-Minneapolis and Vancouver samples (17, 22). Second, results of genetic analyses were similar when all three samples were used or the Minneapolis sample was excluded. Third, the same significance test results for model adequacy occur from including or excluding the Minneapolis sample. Therefore, sample heterogeneity does not account for our findings. We would have tested genetic models for the Minneapolis sample alone to check this further, but the sample was too small.

There were no significant sex differences on root mean square error for members of schizophrenic patients' families. While the age effect was significant, it accounted for just 4% of the variance. Analyses of age- and sex-adjusted data were completely consistent with those from raw data, so only raw data are used here.

Root mean square error was positively skewed (coefficient of excess=2.72). The estimated parameters required to eliminate skewness in comparison subjects were $\lambda_1=-0.24$ (power parameter) and $\lambda_2=-36.50$ (offset parameter). This means that the lower the transformed score, the worse the eye tracking performance.

We looked for evidence of assortative mating. The estimated spousal correlation (after allowing for genetic transmission) was -0.36 ($SD=0.34$, not significantly different from zero ($\chi^2=0.93$, $df=1$, $p<0.40$)). We also tested whether parent-offspring and sibling-sibling correlations differed. If they did, then we would need to fit these correlations separately. They were estimated as 0.29 and 0.32, respectively, not significantly different ($\chi^2=0.16$, $df=1$, $p<0.70$). Therefore, in further analyses

^aq=Frequency of genetic allele A causing eye tracking dysfunction.

^b μ_{AA} , μ_{AB} , μ_{BB} =Transformed root mean square errors for major genotypes. High scores indicate good eye tracking.

^c σ^2 =Within-genotype variance.

^d τ_{AA} , τ_{AB} , τ_{BB} =Probabilities of transmitting an "allele" A for major genotypes.

^erho=correlation due to nonmajor gene (polygenic-like) effect.

^fA significant value means that a model can be rejected. Values for all but the environmental model are for a test of the specified model against the mixed model. The environmental model was evaluated against the free taus model (see text for explanation).

^gEqual to the number of constrained parameters in the tested model; parameters are not constrained in the comparison model.

^hParameter was constrained (for residual model, all μ s set equal; for the environmental model, all τ s set equal).

ⁱdf=2 because τ_{AA} in the free taus model was constrained to the boundary value 1 during maximum likelihood iterations.

we assumed that assortative mating was absent and that there was only one distinct correlation rho to be estimated, to which parent-offspring and sibling-sibling correlations were equal.

Segregation Analyses

Results appear in table 3. Column heads denote genetic parameters (see earlier discussion). In the three columns headed " $\tau_{AA}/\tau_{AB}/\tau_{BB}$," each row specifies a different model. A significant χ^2 means that a model can be rejected.

Before we can test the genetic hypotheses of interest, we need a null hypothesis model to serve as a yardstick. This model should be one that fits the data parsimoniously. It must include parameters corresponding to all the genetic models that we wish to test. If it does not, differences between log-likelihoods for the models being compared will not generally be distributed as χ^2 and we cannot compute significance levels.

Therefore, the first lines of table 3 compare two candidate null models, the free taus and mixed models. Both models are very general, having a major gene as well as polygenic-like effects. The free taus model differs from the mixed model in that the former allows the "gene" not to act like a real gene. That is, its segregation is not required to be Mendelian. We illustrate this difference with an example: in the mixed model, the offspring of an AB genotype \times AB genotype mating are required by Mendel's laws to have genotypes AA, AB, and BB in proportions $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$ (ignoring sampling variation), which proportions are generated by the assumption that $\tau_{AB}=0.5$. Also in the mixed model, an AA \times AA mating can produce only AA offspring because each parent transmits the allele A to all its offspring (symbolized $\tau_{AA}=1$); similarly, $\tau_{BB}=0$ under the mixed model. By contrast, in the free taus model, the τ s may

lie anywhere between zero and one. Therefore, the comparison between the first two tabled lines tests whether the major "gene" acts like a real gene and follows Mendel's laws.

In fact, the mixed model fits as well as the free taus model. Furthermore, the estimated τ_{AB} (first line) lies within 1 SE (0.38, SE=0.39) of its theoretical value, 0.5. Therefore, the inference that the major gene shows true Mendelian segregation is supported. This implies that the mixed model is the best standard against which to test the nonenvironmental models below it.

The next line, "Environmental," tests for the presence of vertical (parent-offspring) transmission. In this model, there are three potentially distinct grades of eye tracking performance, but parental performance is not required to predict offspring performance. This is concretely modeled by assuming that, no matter what the parental "genotype," the probability of transmitting the tendency to have high root mean square error is the same, i.e., $\tau_{AA}=\tau_{AB}=\tau_{BB}$. (The actual value estimated, 0.1, is immaterial here.) Therefore, rejecting this model amounts to affirming parent-offspring resemblance. Because the environmental model contains free parameters (three τ s) that are constrained in the mixed model, the environmental model has, for technical reasons, to be tested against the free taus model rather than against the mixed model. (Since these two models have nearly equal likelihoods, here this makes little difference.) From the p value, we see that there is clearly significant vertical transmission. Therefore, the data are consistent with genetic transmission as opposed to, for example, sibling "contagion."

The next test specific genetic models of interest. The first two lines in the third part of the table test models in which all transmission occurs by a single gene. Whether one assumes that the allele A is dominant ("Dominant") or that heterozygotes can lie anywhere

with respect to homozygotes ("Generalized single major locus" model), single-gene models are rejected. Therefore, the hypothesis of Matthysse, Holzman, and colleagues of strictly dominant major gene action is not supported.

The line labeled "Residual genetic" tests whether non-major-gene (quasi-polygenic) factors alone can account for the data. This model is concretely specified by requiring that the three major genotype groups have the same mean, i.e., by requiring $\mu_{AA}=\mu_{AB}=\mu_{BB}$. Again, the actual estimated value for these μ s, 560.5, is immaterial here. This no-major-gene model is decisively rejected. Therefore, at least one major gene is required to account for the data; the polygenic model advanced by Gottesman et al. (2) for schizophrenia does not fit these eye tracking data. The major gene in the mixed model accounts for 68% of the variance in root mean square error.

In untabled analyses, we also tested variants on the mixed model (second line) to see whether simple Mendelian patterns occurred. Purely dominant, exactly additive, and purely recessive patterns (working in concert with residual genetic influences) do not fit these data ($\chi^2=19.83$, $df=1$, $p<0.001$; $\chi^2=23.83$, $df=1$, $p<0.001$; and $\chi^2=23.83$, $df=1$, $p<0.04$, respectively). However, the favored mixed model, in the second line, is rather close to recessive (μ_{AB} is approximately equal to μ_{BB}).

DISCUSSION

To our knowledge, these data provide the first rigorous evidence for a major gene affecting eye tracking dysfunction. In fact, we believe that this is the first such demonstration for any schizophrenia-related biological trait. (Previously reported linkage of schizophrenia to chromosome 5 markers has not replicated.) Our results imply that schizophrenia itself may be influenced in some families by at least one single major gene (despite the inconsistent linkage data). Eye movement dysfunction may help detect gene carriers, potentially improving prospects for genetic analysis. This gene would presumably affect the risk of schizophrenia, but we decline at present to speculate how this might occur.

Matthysse, Holzman, and colleagues' dominant gene theory for eye tracking dysfunction and schizophrenia does not adequately fit our data in that their model proposes dominant gene action alone, while we find recessive action in addition to polygenic-like transmission. However, our results clearly and strongly support their central tenet, namely, a single major gene that influences eye tracking.

Our data do not prove that a single gene is at work. First, replication is needed. Second, other causes of apparent Mendelian segregation need to be considered. For example, McGuffin and Huckle (39) recently facetiously reported finding "the recessive gene for attending medical school." They "showed" that a major gene accounts for the familial nature of becoming a doctor. This example, while sobering, does not cast serious

doubt on our results. Attending medical school is clearly a function of many influential life events, while eye tracking dysfunction is not subject to social selection or influence as far as we know. It is implausible that nongenetic factors happen to mimic a major gene for eye tracking dysfunction.

The potential role of platykurtosis (flattening of the distribution of eye tracking dysfunction scores) also needs to be considered. Eaves (40) gave examples in which correct/incorrect psychological test item scores are cumulated into a total score. If items are very good at discriminating whether individuals possess more or less than a specific (arbitrary) amount of the underlying ability measured by the test, then grossly platykurtotic scores can be found because the test has a distorted measurement scale. If the tested ability is heritable and if such a variable is subjected to segregation analysis, Mendelian segregation could be simulated. However, this is also not a major threat to our conclusions. Our data show not just platykurtosis but replicated outright bimodality (17, 22). This is hard to account for by deficiencies in scaling of the eye tracking dysfunction measure.

Objections might be raised that we should not have transformed our data before segregation analysis. Deciding whether to transform data can be a difficult problem. As pointed out earlier, analysis of untransformed but skewed scores can lead to false positive findings of major gene action. However, it is also true that transforming data to reduce skewness could lead to false negative results, at least when a very common gene of relatively modest effect is at work. Since the effect of transformation, then, is to lower power to detect a single major gene (without raising the risk of falsely finding a gene), and since our results strongly favor a major gene hypothesis, the problem of whether to transform the data does not vitiate our conclusions.

Our data also do not prove that only one major gene accounts for eye tracking dysfunction. Our models allow for heterogeneity only in having both polygenic and major gene causes of eye tracking dysfunction. We were not able to evaluate models that postulate two- or three-gene action. Study of such possibilities awaits general availability of more sophisticated computer programs.

An eye tracking gene may not account for most of the variance in schizophrenia risk. We have shown elsewhere (22) that eye tracking dysfunction accounts for approximately 25% of the variance in risk for a spectrum diagnosis (schizophrenia in addition to schizotypal personality) in schizophrenic patients' families. Any gene discovered here is probably only one cause of schizophrenia.

The analysis of eye tracking and other biological traits related to familial risk for schizophrenia may serve two useful functions. First, it may help us account for more of the risk for this disorder. Second, it may help break down the complex clinical presentation of schizophrenia into more simply inherited biological abnormalities.

Effects of Sodium Lactate Infusion on Cisternal Lactate and Carbon Dioxide Levels in Nonhuman Primates

Jeremy D. Coplan, M.D., Tarak Sharma, Ph.D., Leonard A. Rosenblum, Ph.D.,
Steven Friedman, Ph.D., Trina B. Bassoff, M.A.,
Randall L. Barbour, Ph.D., and Jack M. Gorman, M.D.

***Objective:** To further the understanding of lactate-induced panic in patients with panic disorder, the authors examined cisternal lactate and carbon dioxide levels in nonhuman primates after infusions of sodium lactate comparable to those used in studies of human beings. **Method:** CSF and venous blood lactate, pH, PCO₂, PO₂, and bicarbonate were measured in five ketamine-anesthetized nonhuman primates, without mechanical ventilation, before and after they underwent infusions of sodium lactate. In addition, the same measurements were made for three of the five subjects who were given saline infusions. **Results:** Despite the development of the characteristic peripheral biochemical effects of infused sodium lactate—increased lactate and bicarbonate levels and metabolic alkalosis—no increases in central lactate or carbon dioxide levels were observed. Saline infusions produced no biochemical effects on venous and cisternal measures. **Conclusions:** The results of this study are in keeping with previous findings of nonpermeability of the blood-brain barrier to anionic compounds such as lactate. They therefore support theories of lactate panic based on cognitive and/or brainstem miscalculation of peripheral somatic sensations.*

(Am J Psychiatry 1992; 149:1369–1373)

Patients with panic disorder (1, 2) and patients with histories of panic attacks (3) are susceptible to the panicogenic effects of sodium lactate infusion. Despite the clinical and heuristic importance of the lactate panic model, mechanisms for lactate-induced panic remain unclear.

Hypotheses for lactate-induced panic have focused primarily on peripheral metabolic effects, especially since studies have suggested that lactate, largely ionized at a normal pH, does not freely cross the blood-brain barrier (4–7). Dager et al. (8), however, reported an increase in CSF lactate in baboons after infusion of 1.0 M racemic sodium lactate at 10 ml/kg, suggesting that infusion of sodium lactate may directly affect the CNS in inducing panic. However, examination of the methodology of

Dager et al. (8) raises several issues. First, the animals were mechanically ventilated, thus presenting the possibility of inadvertent hypoventilation and a consequent increase in central lactate levels secondary to hypoxia. Second, the animals were anesthetized with halothane, an agent that can alter blood-brain barrier permeability (9–11). Third, the amount of lactate infused was double that which is generally used in the standard clinical procedure for humans. It is possible that this high concentration may have exceeded a threshold for blood-brain barrier permeability to lactate.

The question therefore remains whether sodium lactate, infused at concentrations that trigger panic in susceptible humans, penetrates the blood-brain barrier. If it does so in significant amounts, theories of lactate-induced panic would have to include (or discard) direct CNS effects.

Another theory for lactate panic has been postulated by Klein et al. (unpublished 1985 paper). They hypothesized that peripherally infused sodium lactate stimulates production of bicarbonate, which is metabolized to carbon dioxide and water. The model is based on the fact that bicarbonate penetrates the blood-brain barrier poorly, whereas carbon dioxide traverses readily (12). These authors suggested that central hypercarbia triggers an abnormally sensitive “suffocation alarm mechanism” in patients with panic disorder, leading to

hyperventilation, a fear of suffocation, and a desire to flee. This central hypercarbia is putatively responsible for the panicogenic effects of lactate (13), inhaled carbon dioxide (14), and infused bicarbonate (15). However in a test of this hypothesis in halothane-anesthetized baboons, Dager et al. (8) failed to find an increase in CSF carbon dioxide levels following racemic lactate infusion.

In an effort to resolve some of the critical questions raised by the findings of Dager et al. (8), we examined lactate distribution and metabolism in nonhuman primates by monitoring cisternal measures after saline and sodium lactate infusions. Ketamine anesthesia was used in this study to avoid the need for mechanical ventilation, and a racemic lactate infusion, paralleling the concentration used in human studies, was administered.

METHOD

Five adult male Bonnet macaques (*Macaca radiata*) served as subjects. Their mean weight was 7.72 kg (SD=0.97, range=6.6–9.3), and their mean age was 5.83 years (SD=0.75, range=5–7). All five subjects underwent 0.5 M lactate infusions, and one subject underwent a repeat 0.5 M lactate infusion. Three of the five subjects also underwent saline infusions, and one of these three subjects subsequently received a 1.5 M lactate infusion.

After transfer from their home cage to a squeeze cage, the subjects were rapidly injected with ketamine, 10 mg/kg i.m. Once anesthetized, the animals were transported to a surgical area and observed for a period of 40 minutes before the first blood and CSF sampling. In general, the animals required 50 mg i.m. of ketamine every half-hour to maintain adequate anesthesia. In the case of replicated procedures (saline or lactate), the timing of ketamine injections was matched to that used in the animal's previous procedure. At least 7 days intervened between trials. On the basis of pilot data, the 40-minute delay before sampling was instituted to avoid the possibility that endogenously produced lactate resulting from the capture procedure would obscure assessment of the exogenous infused lactate. Under these conditions, endogenous serum lactate levels return to baseline by 40 minutes after capture.

After 40 minutes, 3 ml of venous blood were drawn for determination of serum lactate levels and blood gas measurement (pH, PCO₂, PO₂, bicarbonate level, and oxygen saturation). In addition, 2 ml of CSF were obtained, by cisternal tap with a 3/4-inch 23-gauge needle, for making the same measurements. Once the fluid samples had been obtained, either racemic sodium lactate (0.5 M, 10 ml/kg) or an equal volume of 0.9% saline solution was infused intravenously at a constant rate for a total of 20 minutes. (To assess the possibility that membrane permeability might be enhanced at a considerably higher concentration, an infusion of 1.5 M lactate, 10 ml/kg, was administered to one of the subjects who had been tested at the lower level.) Immediately following the infusion, samples were again obtained for making the same measurements that had been made before infusion. (Similarly, to determine whether ketamine anesthesia might reduce permeability to the lactate, one subject was tested according to a different procedure. This subject was manually restrained and infused with 0.5 M lactate before ketamine administration. After the 20-minute infusion, this subject was anesthetized with ketamine as described, and a CSF sample was drawn.) Fluids for gas measurements were collected in heparinized syringes, immediately stored on ice, and assayed shortly afterward. Samples for lactate measurements were collected in tubes with sodium fluoride anticoagulant and assayed immediately.

Levels of L-lactate were measured with the Du Pont automatic clinical analyzer (16). This method is a modification of the Marbach and Weil method (17), which uses the oxidation of lactate to pyruvate by rabbit muscle lactic dehydrogenase. Gas measurements were performed on a radiometer ABL3 blood gas analyzer. The precision of measurement for all determinations (pH, PCO₂, PO₂) had a coefficient of variation of less than 2%. Bicarbonate level and hemoglobin oxygen saturation are calculated from these measurements.

We used t tests to compare preinfusion blood and CSF measurements (means were used for repeated procedures) and to compare serum and CSF lactate, PO₂, PCO₂, pH, and bicarbonate levels before and after lactate infusion. Since only three subjects received the saline infusion, conclusions were drawn from the findings of this procedure after inspection only.

RESULTS

At baseline, venous blood lactate levels were significantly lower than CSF lactate levels, whereas blood pH was significantly higher than CSF pH (table 1). PO₂ was consistently higher in CSF than in venous blood, whereas there was a trend for higher PCO₂ in CSF than in venous blood. Bicarbonate levels were consistently lower in CSF than in venous blood. Thus, in accordance with findings in previous studies (18), we found that CSF is relatively acidotic and arterialized and has high lactate levels when compared to venous blood.

As reflected in figure 1 and table 2, serum lactate lev-

FIGURE 1. Effects of Lactate Infusion on Venous and Cisternal Measures in Five Nonhuman Primates

els increased more than tenfold after lactate infusion. (It should be noted that all three subjects who had infusions of saline showed a decrease in lactate levels after infusion: mean=0.97 mmol/liter, SD=0.45, before infusion; mean=0.50 mmol/liter, SD=0.17, after infusion. This suggests that the animals had still not fully reached basal levels of serum lactate even 40 minutes after capture, nor had the ketamine anesthesia stimulated anaerobic metabolism.) In contrast to the enormous rise in serum lactate after lactate infusion, there was no significant increase in CSF lactate levels. Although four of the five subjects showed a minimal increase in CSF lactate levels, it should be noted that two of three subjects also showed similar minimal increases following infusion of saline (overall means were 1.77 mmol/liter, SD=0.15, before infusion and 1.87 mmol/liter, SD=0.12, after infusion).

The subject receiving the 1.5 M concentration of lactate showed an increase in blood lactate from 1.9 mmol/liter to 26.4 mmol/liter (triple the level observed in this subject after the 0.5 M infusion). Nonetheless, the subject's CSF lactate level rose only modestly, from 1.9 to 2.6 mmol/liter (compared to an increase from 1.9 to 2.1 mmol/liter after the 0.5 M infusion). Thus, a

^aMean values for a subject who had two 0.5 M lactate infusions have been included.

1289% increase in venous serum lactate was associated with only a 36% increase in CSF lactate. Similarly, the restrained subject infused before receiving ketamine showed only a minimal rise in CSF lactate despite blood lactate levels triple those of the anesthetized subjects (undoubtedly because of heightened endogenous lactate production due to muscular activity).

There was a significant increase in blood pH following lactate infusion (table 2), whereas pH dropped modestly in all three subjects after saline infusion (mean=7.44, SD=0.01, before infusion and mean=7.42, SD=0.01, after infusion), probably due to a respiratory-depressant effect of the ketamine. CSF pH levels remained quite stable from before lactate infusion to after infusion (table 2). After 1.5 M infusion, the subject's peripheral pH increased from 7.46 to 7.70, whereas cisternal pH remained relatively constant (7.32 to 7.35).

Blood measurements of PCO₂ before and after lactate infusion did not differ significantly (figure 1 and table 2), nor were there any effects of the saline infusions (mean=46.90 mm hg, SD=1.30, before infusion and mean=48.40 mm hg, SD=2.70, after infusion). Similarly, CSF PCO₂ values before and after lactate infusion were not significantly different (figure 1 and table 2), nor did they differ after saline infusion (mean=47.80 mm hg, SD=4.40, before infusion and mean=51.80 mm hg, SD=1.60, after infusion). Following 1.5 M lactate infusion, the subject's central PCO₂ also remained relatively unchanged (45.50 mm hg to 44.90 mm hg).

Serum bicarbonate levels increased following lactate infusion (table 2) but were relatively unchanged following saline infusion (mean=31.73 mmol/liter, SD=0.15, before infusion and mean=29.43 mmol/liter, SD=4.01, after infusion). In spite of the significant increases in serum bicarbonate after lactate infusion, CSF bicarbonate levels increased only modestly following lactate infusion (table 2); following saline, the mean level increased from 24.37 mmol/liter (SD=0.15) to 29.43 mmol/liter (SD=4.01). After the 1.5 M infusion, the ani-

mal's peripheral bicarbonate level rose from 32.00 to 45.20 mmol/liter, whereas the central bicarbonate level remained relatively stable (22.90 to 24.30 mmol/liter).

No clear pattern of response was observed in blood or CSF PO_2 measures in either infusion condition.

DISCUSSION

The peripheral measures were generally in accordance with those obtained in clinical lactate infusions (1, 2). Increased blood lactate was accompanied by metabolic alkalosis and an increase in bicarbonate levels. In contrast to clinical lactate infusions, however, there was no consistent evidence for hyperventilation on venous PCO_2 , PO_2 , or oxygen saturation measures, although arterial samples are generally required for making an accurate assessment of respiratory function. The absence of increased serum lactate levels and decreased venous pH following the saline infusions suggests that there were no significant respiratory-depressant effects of ketamine.

Despite the induction of the characteristic peripheral effects of lactate infusion, there were no consistent central effects. These negative findings included the absence of cisternal increases in lactate or PCO_2 levels following infusion of lactate. A previous study (8) had reported an increase in cisternal lactate following lactate infusion despite unchanged carbon dioxide levels. Other studies, however, have suggested that the blood-brain barrier is not readily permeable to lactate. For instance, peripherally infused lactate failed to reverse hypoglycemic coma in humans or hypoglycemic seizures in dogs (19), and there are no consistent relations between blood and CSF lactate levels in these two species (18, 20).

Our findings, therefore, are consistent with those of most previous studies but differ from those of Dager et al. (8) with respect to the CSF lactate findings. Several methodological differences may account for this discrepancy. First, Dager et al. infused a 1.0 M concentration of sodium lactate, whereas we used a 0.5 M concentration in the major portion of this study, a level most commonly used with humans. In work with primates, a panic-like pattern, which we term "acute endogenous distress," has been successfully produced with the lower dose (21). Acute endogenous distress is defined as a temporally circumscribed period of motoric agitation and affective distress in the absence of external threat. It is possible that high concentrations of lactate, delivered rapidly, as in our 1.5 M infusion, may be accompanied by modest increases in cisternal lactate, perhaps by exceeding a particular threshold for membrane permeability (8) or as a result of nonspecific osmotic stress (22). The phenomenon, however, does not appear relevant to procedures capable of producing lactate panic in humans.

It should be noted that Dager et al. (8) measured L-lactate and D-lactate combined, whereas only L-lactate was measured in this study. However, Dager et al. (un-

published 1989 paper) indicated that following infusion of high concentrations of racemic lactate, less D-lactate than L-lactate was detected in CSF. Given the absence of an increase in cisternal levels of L-lactate at the 0.5 M concentration, it seems unlikely that D-lactate penetrated the barrier in significant quantities in the current study.

Another source of variation in the findings of various studies concerns the type of anesthetic used. Halothane, used by Dager et al. (8), increases blood-brain barrier permeability to glucose (9) and cocaine (10), although this may only be relevant during conditions of hypocapnia (11). Other studies have used either pentobarbital (20) or, as in this study, ketamine. There is a suggestion (23) that in rats, both agents may reduce blood-brain barrier permeability to a circulating tracer, [^{14}C] α -aminoisobutyric acid. In this study we observed no indication of reduced permeability to lactate due to ketamine.

The absence of a rise in cisternal carbon dioxide in the face of substantially increased systemic lactate and bicarbonate levels is a consistent finding (8, 20). Thus, it appears unlikely that central hypercarbia is a consistent factor in lactate panicogenesis. Most panicogenic agents administered to humans, including racemic lactate (2), D-lactate (24), carbon dioxide (14), sodium bicarbonate (15), isoproterenol (25), caffeine (26), and cholecystokinin (27), produce panic-associated respiratory stimulation. The current and previous studies (8, 20) suggest, however, that peripheral factors may be important for stimulation of the hypothesized hypersensitive suffocation alarm mechanism, but we lack sufficient information at present to substantiate an explanation for lactate panic through peripheral mechanisms.

The data from this study can be seen as supporting a cognitive-behavioral perspective of lactate-induced panic. This model suggests that lactate infusion produces peripheral somatic sensations analogous to naturally occurring panic attacks, which the subject then interprets as an indication of an impending internal catastrophe. Cognitive-behavioral therapy is presumably effective in blocking lactate-induced panic (28) by modifying thoughts of impending catastrophe despite the induction of distressing peripheral somatic sensations.

Alternatively, peripheral cardiovascular stimulation without changes in pH (e.g., with isoproterenol [25]) or activation of chemoreceptors without direct cardiovascular effects (e.g., with carbon dioxide [14]) appears capable of provoking panic. In the case of sodium lactate, both chemical and cardiovascular factors are relevant. In this model, vagally mediated information from the periphery is conveyed to the nucleus tractus solitarius and then to other brainstem structures (13), where it is presumably erroneously evaluated as noxious, triggering both panic and panic-specific respiratory stimulation. These brainstem events may secondarily lead to a cognitive perception of impending catastrophe.

Future studies in nonhuman primates should prove useful in explicating the contribution of both physiological and behavioral-cognitive elements to the elici-

tation of panic. It is essential that we attempt to characterize the neurochemical and pharmacological factors that may be responsible for erroneous information processing at brainstem sites and examine cognitive interventions that may influence interpretation of potentially distressing somatic stimuli.

Bereavement Reactions Among Homosexual Men Experiencing Multiple Losses in the AIDS Epidemic

Richard Neugebauer, Ph.D., M.P.H., Judith G. Rabkin, Ph.D., M.P.H.,
Janet B.W. Williams, D.S.W., Robert H. Remien, Ph.D.,
Raymond Goetz, Ph.D., and Jack M. Gorman, M.D.

***Objective:** The authors examined whether deaths of lovers and close friends from AIDS increased the frequency of depressive symptoms and depressive disorder in a group of homosexual men. **Method:** Two hundred seven volunteer male homosexual subjects were interviewed in New York City in 1988 and 1989. Depressive symptoms were measured with the Hamilton Rating Scale for Depression, administered by a clinician, and two self-report symptom checklists. Subjects were evaluated for major depression with the Structured Clinical Interview for DSM-III-R. Each subject also reported the number of lovers and close friends who had died of AIDS 1) since the beginning of the epidemic in 1981 and 2) in the 6 months preceding the interview. **Results:** Neither the overall level of depressive symptoms, the presence of specific symptom clusters, nor the presence of a diagnosed depressive disorder was related to the number of AIDS deaths a subject reported in either time frame. In contrast, bereavement reactions specific to loss, namely, preoccupation with and searching for the deceased, were more common in subjects with greater numbers of losses. The findings for depressive symptoms and major depression are not readily explained by measurement artifact, overrepresentation of asymptomatic subjects among study volunteers, habituation effects, numbness, or shallowness of attachments in the subjects. **Conclusions:** Changes in normative expectations regarding AIDS deaths and mobilization against AIDS within the gay community may account for the lack of association between the number of losses resulting from AIDS and the presence of depressive symptoms and depressive disorder.*

(Am J Psychiatry 1992; 149:1374-1379)

The gay community in the United States has been devastated by the AIDS epidemic. As a consequence, many homosexual men, irrespective of whether they themselves are seropositive for HIV infection, have experienced multiple losses of friends and lovers (1-4). The classic works on bereavement document that loss of a loved one typically produces a range of depressive symptoms. Lindemann (5), Parks (6), Clayton (7), and others (8-12) have described affective, vegetative, and psychophysiological symptoms among bereaved spouses that persisted for at least a year after the death of the partner. An annual incidence rate of 47% for a full depressive syndrome in bereaved spouses has been

reported, representing a sixfold increase over that in a comparable nonbereaved sample (13). Such findings raise concerns that bereaved homosexual men may be at especially high risk for these depressive reactions to loss. Alleviating such responses is an immediate clinical concern. Furthermore, since depression may increase high-risk behavior and reduce compliance with antiviral drug treatments, determining the scope of depressive symptoms and possible moderating factors is of considerable public health importance.

The study reported here examined the effect on homosexual men of multiple losses associated with the AIDS epidemic. In addition to our interest in the clinical and public health aspects of this area, we undertook this investigation as part of a larger effort to expand bereavement research beyond the well-documented areas of spousal, parental, and child death (14, 15).

METHOD

The subjects of this investigation were participants in a study of risk factors for HIV disease progression con-

ducted in New York City. Recruitment was accomplished through announcements in gay organization newsletters, a newspaper advertisement, and, thereafter, word of mouth (each method secured about one-third of the subjects). Participants were restricted to homosexual or bisexual men aged 18–60 years who had been aware of their HIV serological status for at least 1 month before entering the study. Persons meeting the Centers for Disease Control national surveillance criteria for AIDS (16, 17) were excluded, except for those with esophageal thrush (18).

The baseline examinations, conducted between March 1988 and March 1989, included medical, psychiatric, and psychosocial assessments, supplemented by psychiatric and psychosocial self-rating forms completed approximately 1–2 weeks earlier. Details of the full test battery are presented elsewhere (18–20).

For this study of bereavement reactions, by the term “bereavement” we denote the fact of loss through death of a person to whom one is emotionally attached (21). On the basis of the clinical literature, we decided to examine two conceptually distinct dimensions of psychological response to bereavement: 1) depressive reactions covering a range of affective, somatic, and cognitive complaints that may be sufficiently severe to meet criteria for major depressive disorder and 2) thoughts and feelings specifically focused on the deceased that we denote as preoccupation with and searching for the deceased.

Preoccupation and searching were assessed with the 13-item section on current feelings in the Texas Revised Inventory of Grief (22). This section focuses on the presence of the following subjective experiences at the time of interview: preoccupation with and searching for the deceased (e.g., “I can’t avoid thinking about the person who died”; “Things and people around me still remind me of the person who died”) (four items); tearfulness at the thought of the deceased (e.g., “I still cry when I think of the person who died”) (three items); inability to accept the death (e.g., “I am unable to accept the death of the person who died”) (two items); distress and pain when thinking of the deceased (e.g., “I still get upset when I think about the person who died”; “Even now it’s painful to recall memories of the person who died”) (three items); and anger at the death (“I feel it’s unfair that this person died”) (one item). Items are scored from 1 to 5, with higher scores reflecting more feelings of this type. Item wording was modified only to adjust for the possibility of multiple decedents.

Depressive symptoms were measured with the Hamilton Rating Scale for Depression (23), the depression subscale of the Brief Symptom Inventory (24), and the Demoralization Scale (25); major depression was assessed with the Structured Clinical Interview for DSM-III-R (SCID) (26). The first and last measures were administered in person by a clinician; the middle two are self-report instruments.

The Hamilton scale (17 items) covers the major domains of depressive symptoms in the week preceding interview. Substantial attention is given to somatic

complaints. Scores range from 0 to 53, with scores below 7 indicating lack of clinically significant depressive symptoms. Administration of the scale in this study was aided by the use of a structured interview guide (27) to improve reliability.

The Brief Symptom Inventory is a 53-item rating scale derived from the SCL-90. Its seven-item depression subscale covers dysphoric mood, loss of interest in usual activities, and other nonvegetative symptoms in the preceding week. Scores, expressed as the average item score, range from 0 to 4, with higher scores signifying a greater number of symptoms. Mean scores of approximately 1.8 have been reported for depressed psychiatric outpatients (24).

The Demoralization Scale is a 27-item measure of psychological distress designed for use in the general population. It includes highly intercorrelated symptoms of depressed affect, feelings of low self-esteem, psychophysiological disturbance, and anxiety. Scores can range from 0 to 108; the time frame adopted for this study was the 6 months preceding interview. The mean score in a New York City community sample was approximately 28 (28). Since scores on this scale correlate highly with self-report measures of depressive symptoms (29), in this article scores on this scale are treated as reflecting numbers of depressive symptoms.

The SCID was used to assess the presence of a current episode of major depression. This instrument is a general clinical interview guide that enables clinicians to secure information appropriate for arriving at a diagnosis according to *DSM-III-R*. All interviewers were clinicians with degrees at the master’s level or above who had had extensive previous clinical experience. Interviewer training has been described in detail elsewhere (19). In general, the interviewers were not blind to the subjects’ bereavement status.

In the interview, in response to a modified version of questions developed by Martín (30), each subject enumerated lovers, former lovers, and close friends who had died of AIDS. Each question was asked with reference to the entire period since the start of the epidemic in 1981 and to the 6 months preceding the interview.

The association of number of losses with preoccupation and searching and with depressive symptoms was examined in one-way analyses of variance (ANOVA) using the two-tailed test for linearity with 1 degree of freedom. The association of number of losses with current major depression was tested by using maximum likelihood logistic regression. Losses since the onset of the epidemic were examined first, then losses just in the 6 months preceding interview. (Since preoccupation and searching are specific to persons with loss, the relative rarity of persons with more than one loss in the 6 months preceding interview precluded an analysis of this measure for this shorter time period.) In analyses covering the entire epidemic, numbers of losses were grouped into zero, one, two, and three or more to permit direct comparison with prior research (30). For the 6 months preceding interview, numbers of losses were grouped as zero and one or more. Associations involv-

Total ^b	161	79.3	34	16.7	5	2.5	3	1.5

^aData on some categories of loss are missing for two subjects.

^bThe number of individuals listed in the total in each column does not equal the sum of the numbers in that column because subjects are often enumerated in more than one category of reported loss in a given column.

^cData on some categories of loss are missing for four subjects. These losses are included in the numbers reported for the entire epidemic.

ing continuous variables as the outcome measure of interest—namely, preoccupation and searching, Hamilton depression score, Brief Symptom Inventory depression score, and Demoralization Scale score—were further evaluated using least squares hierarchical multiple regression to afford control of potentially confounding variables, i.e., factors that might be correlated both with losses and with the outcome measure. Such factors—namely, age, HIV status, early signs or symptoms of HIV infection (7), and instrumental and emotional supports—were entered as covariates (in that order) in the regression equation, followed by number of AIDS losses. The measure of social support, derived from Wortman's Social Support Scale (31), assessed levels of emotional and instrumental support available to study subjects in the past month. Associations using major depression, a dichotomous variable, as the outcome were examined again by means of logistic regression, introducing the same covariates as in the least squares regression analyses. Screening of the data for other confounding variables disclosed no additional factors requiring adjustment. In all analyses, statistical significance was established as $p < 0.05$.

RESULTS

The study group consisted of 207 men, 84 HIV negative and 123 HIV positive. In the latter group, 48 men were asymptomatic, 28 were mildly symptomatic, and 47 had significant medical symptoms but not AIDS. The mean age was 38.1 years ($SD=8.5$); 87% ($N=179$) were white, 7% ($N=15$) were Hispanic, and the remainder were black or Asian. The mean number of years of education was 16.4 ($SD=2.7$).

Half of the group reported one or more losses since the start of the epidemic (table 1). Over 20% had experienced a loss in the 6 months preceding interview. These proportions were similar for HIV-positive and HIV-negative subjects.

Preoccupation and searching rose with increasing numbers of losses (of lovers, former lovers, and close friends combined) since the start of the epidemic (table 2). These results were sustained in multiple regression analyses and did not vary by HIV status.

By contrast, the subjects' levels of depressive symptoms did not increase with greater numbers of losses since the start of the epidemic. This result held separately for the Hamilton depression scale, the Brief Symptom Inventory depression subscale, and the Demoralization Scale (table 2) and was unchanged in multiple regression analyses. The possibility of a curvilinear relationship, whereby, for example, Hamilton depression scores rise significantly with the first loss and then decline thereafter, was tested in the multiple regression setting and rejected. The lack of association between loss and depressive symptoms held for the HIV-positive and the HIV-negative men separately.

Similar results were obtained in the analyses of major depression. The overall rate of 3.4% did not vary significantly by number of losses for all subjects combined (table 2) or when subjects were stratified by HIV status. Results from logistic regression analyses adjusted for potential confounding variables produced much the same findings.

Men with and without losses in the 6 months preceding interview did not differ on levels of depressive symptoms or major depression. For example, the mean Hamilton depression score of men bereaved in the preceding 6 months was 3.4, and that of men without recent losses was 4.0. Of the recently bereaved men, 2.4% met criteria for current major depression, compared with 3.6% of those who had not experienced recent losses.

Each of these results for depressive symptoms and depressive disorder persisted in analyses performed separately for loss of lovers, loss of former lovers, and loss of close friends and for subgroups of items on the symptom inventories pertaining separately to depressed affect, somatic complaints, and low self-esteem.

TABLE 2. Preoccupation and Searching, Depressive Symptoms, and Major Depression in 207 Male Homosexual Subjects by Number of Lost Relationships Since the Start of the AIDS Epidemic in 1981

Measure	Total Group of Subjects		Subjects Reporting No Loss		Subjects Reporting One Loss		Subjects Reporting Two Losses		Subjects Reporting Three or More Losses	
	Mean	SD	Mean	SD	Mean	SD	Mean	SD	Mean	SD
Score on preoccupation and searching ^a	32.4	10.6			30.2	11.3	32.2	8.6	35.2	10.5
Hamilton depression score ^b	3.9	3.9	3.8	4.2	4.7	3.8	3.3	3.1	3.3	3.8
Brief Symptom Inventory depression score ^b	0.9	0.8	1.0	0.8	0.8	0.7	0.7	0.9	0.8	0.8
Demoralization Scale score ^b	32.9	17.5	34.3	16.8	32.4	18.3	33.3	21.3	29.4	16.1
Percentage of subjects with current major depression ^c	3.4	1.3	3.0	1.7	4.4	3.1	0.0	0.0	5.4	3.7

^aScores start at the level of one AIDS loss rather than none, since this scale measures reactions specific to bereavement. ANOVA test for linearity, $F=4.45$, $df=1, 101$, $p<0.04$.

^bANOVA test for linearity showed no significant difference.

^cMaximum likelihood logistic regression coefficient was not significant.

DISCUSSION

Among our study subjects, men with greater numbers of losses reported more subjective experiences characteristic of preoccupation with and searching for the deceased than did men with fewer losses. While these findings agree with common sense, previous studies that have described forms of searching for and preoccupation with the deceased have examined reactions to single losses only—most commonly, death of a spouse. As a result, direct comparison of our results with those from other studies is not possible.

In contrast, neither level of depressive symptoms nor rate of diagnosed depressive disorder was related to number of losses, irrespective of type of loss (lover, former lover, close friend) or recency. Even the mean Hamilton depression score for men who had experienced three or more losses was well below the threshold of clinical significance. This result seems counterintuitive and contradicts previous findings in research on bereavement, at least with regard to reactions to a single loss (5–12). While the absence of any discernible effect of losses on depressive disorder may be attributable to limited statistical power, these findings are entirely consistent with the findings for depressive symptoms, and these latter results cannot be as readily discounted. In the following discussion we consider possible mechanisms that would render our results spurious.

Our findings do not arise from psychometric insufficiencies in our symptom measures; the reliability of all three measures is well established (23–25, 32, 33). In our study group, the internal consistency reliabilities of the Brief Symptom Inventory depression subscale and the Demoralization Scale were 0.90 and 0.94, respectively. (Assessment of reliability of the Hamilton depression scale, usually accomplished through interrater studies, was not undertaken.) The Hamilton scale is the most widely used measure of depressive symptoms in clinical research. The Brief Symptom Inventory is used extensively with psychiatric, general medical, and cancer patients (34). Evidence of these two instruments' concurrent and construct validity is substantial. Fur-

thermore, the concordance in our results across the three different scales, as well as with the results of the SCID, excludes artifacts of setting, method of administration, scale length, specific time period and duration of time targeted by the scales, and scope of symptoms as plausible explanations for these findings. While interviewers were often not blind to the subjects' number of losses, we would expect that, if any clinical bias existed, it would be in the direction of overascertainment of depressive symptoms in bereaved individuals.

The men in our all-volunteer study group may not be representative of homosexual men generally in New York City. The problem of generalizability of results pervades much research on homosexual men. It stems from the fact that no sampling frame exists for this population; hence, no random sample can be drawn. It is reasonable to suppose that volunteers are, in general, less depressed and more capable of adaptive responses to loss than other men in similar circumstances. While such selection bias can not be excluded as the source of our results, collateral evidence from another study and alternative logic argue against this explanation.

In 1985 Martin and colleagues (30, 35) initiated a prospective epidemiologic study of the psychological effects of AIDS losses in a group of 745 homosexual men without AIDS in New York City. The group was assembled through diverse methods, including random sampling from members of gay organizations and personal referrals from the initial subjects. Despite this different recruitment method, the group of Martin et al. and our own subjects were nearly identical sociodemographically. Martin and colleagues have conducted yearly interviews with their study subjects, assessing psychological distress in the preceding year with the Demoralization Scale. In 1987 the mean score on the Demoralization Scale was 31.8, no different from that found in our study group. These similarities in sociodemographic characteristics and symptom levels across the two groups suggest that the groups are drawn from the same underlying population rather than that our study subjects represent a specialized, idiosyncratic subgroup.

If AIDS losses are in fact associated with a rise in depressive symptoms in the larger homosexual population, it is worth considering the nature of the selection bias required to produce the results observed in our study. To achieve our null results, less symptomatic men must have systematically volunteered at an increasing rate at each ascending level of loss. At the same time, this process must have acted only on depressive symptoms, not on preoccupation and searching, since these two manifestations did rise with increasing losses. The complexity of such a mechanism, together with our group's apparently typical sociodemographic characteristics and symptoms, renders the argument for selection bias less compelling. Given these considerations, we conclude tentatively that within certain segments of the gay community during the time period of our study, the experience of multiple AIDS deaths did not increase depressive symptoms.

At least four substantive, as contrasted with artifactual, explanations can be advanced for our findings: habituation, denial or numbness, shallowness of attachments, and protective effects of social supports. None of these explanations accords well with the evidence. Habituation should produce a rise in symptoms after one or perhaps two deaths, followed by a leveling off or a decline—not a consistent absence of effects across all levels of loss. Habituation should also blunt emotional responses to loss generally, whereas growing numbers of deaths did trigger increases in subjective experiences characterized by searching. Subjects' open acknowledgment of preoccupation and yearning effectively excludes the argument for denial or numbness. Similarly, these expressions of searching argue against the notion that the relationships severed by death were shallow attachments. Finally, persons with more losses reported significantly more social support, and social support was associated with lower levels of depressive symptoms and depressive disorder. Nonetheless, the absence of any association between depression and loss persisted after adjusting for these mitigating effects of social support.

While we have little direct evidence in this regard, we speculate that two processes operated to minimize the emergence of depressive symptoms. First, the scale of the AIDS epidemic in the late 1980s meant that the untimely death of friends and lovers was gradually becoming an almost "normal" feature of life among homosexual men. Second, the epidemic produced growing social, cultural, and political mobilization within the gay community as a whole (36), as distinct from an individual respondent's mobilization of his own social network. Our subjects were well aware of these activities and were to some degree participants. For example, 80% reported reading gay newspapers regularly, and over 60% were members of gay organizations. These community activities may offer homosexual men some protection against depressive reactions to multiple losses. The comparatively low rate of current major depression overall in this group—3.4%—affords further support for this conjecture. The expected rate of disorder,

adjusted for age and education level, based on the Epidemiological Catchment Area study data for current major depression in males (unpublished data, National Institute of Mental Health, 1988), would be 2.7%. By contrast, Clayton (13) has reported a rate of 16% for a full depressive syndrome among bereaved spouses 13 months after loss.

These findings would help explain certain other results reported by Martin et al. (35). In 1985, 1986, and 1987 the overall Demoralization Scale mean scores were 35.2, 32.9, and 31.8, respectively. Since these men had experienced additional bereavements after 1985, this decline in symptoms is paradoxical if scores increase with growing numbers of losses. Martin et al. also asked subjects about the number of bereavements they had experienced as a result of AIDS. Whereas in 1985 a strong association emerged between increasing numbers of losses and higher levels of demoralization, that association was absent in 1986 and significantly weaker in 1987 than in 1985. These two sets of results (although not interpreted this way by Martin et al.) are broadly consistent with a pattern of decreasing effects of loss on depressive symptoms in the course of the second half-decade of the AIDS epidemic in the gay community.

Our findings require replication in other study subjects before they can be accepted. However, these preliminary results suggest that the gay community has developed effective coping mechanisms to assist members in dealing with multiple losses. On a more theoretical level, our results also suggest that searching and depressive symptoms are by no means necessarily linked components of the bereavement process. Apparently, under certain social and political conditions, the two sets of bereavement reactions may adaptively disengage.

Need-for-Treatment Criteria for Involuntary Civil Commitment: Impact in Practice

Robert D. Miller, M.D., Ph.D.

There has been considerable discussion in the literature on the differences between criteria for involuntary commitment that are based on dangerousness and criteria based on need for treatment. A number of states have adopted clinical criteria, and other state legislatures are actively considering them. Some libertarians argue that dangerousness is constitutionally required if a person is to undergo the loss of liberty involved in commitment. Citing widely publicized data from the state of Washington, they predict that a return to clinical criteria would result in a deluge of inappropriate commitments. Some clinicians counter that use of clinical criteria would result in selection of a much more appropriate clinical population and point to research indicating that strict observation of the need-for-treatment provisions of the APA model commitment statute would actually decrease the number of commitments. The author examines state hospital admission and census data from eight states that added need-for-treatment criteria to their commitment codes between 1975 and 1990 and argues that the data indicate that there is little reason to believe that such changes would result in the deluge of admissions predicted by the critics.

(Am J Psychiatry 1992; 149:1380-1384)

In the 1970s a series of court decisions, starting with *Lessard v. Schmidt* (1), struck down the existing need-for-treatment criteria for civil commitment as being too broad and too vague. The Hawaii federal district court went so far as to opine that the diagnosis and treatment of mental illness are not acceptable as the basis for commitment because too much is left to subjective choices by individuals who are less than neutral (2).

As a result of such decisions, every state in the country eventually passed statutes making dangerousness to self or to others a requirement for involuntary hospitalization. Many libertarians have concluded that the court decisions indicated that dangerousness was constitutionally required before patients could be deprived of their liberty (3), even though the U.S. Supreme Court has avoided ruling definitively on the issue. In fact, the Court has three times indirectly supported the state's legitimate *parens patriae* interests in providing treatment for those mentally ill who are unable to accept needed treatment because of their illness. In *Jackson v. Indiana* (4), a 1972 case dealing specifically with commitment of persons found incompetent to stand trial, the Court held that "the States have traditionally exer-

cised broad power to commit persons found to be mentally ill The particular fashion in which the power is exercised . . . reflects different combinations of distinct bases for commitment sought to be vindicated. The bases that have been articulated include dangerousness to self, dangerousness to others, and the need for care or treatment or training."

In *O'Connor v. Donaldson* (5), the Court held that "the state cannot constitutionally confine, *without more*, a nondangerous person who is capable of surviving safely in freedom" (emphasis added); the phrase "without more" has generally been interpreted to mean treatment, consistent with the view that provision of effective and needed treatment would be sufficient to justify involuntary hospitalization. Four years later, in *Addington v. Texas* (6), the Court stated, even more directly, that "the state has a legitimate interest under its *parens patriae* powers in providing care to its citizens who are unable because of emotional disorders to care for themselves."

It is true that in its recent decision in *Zinermon v. Burch* (7), the Court, in dicta, cited its previous holding in *O'Connor* but omitted the key phrase "without more," thus again raising questions about its view on commitment for treatment. However, in view of the Court's increasingly clear position in favor of permitting states to set up their own individual procedures to govern admission to their institutions by narrowing the category of legitimate federal constitutional issues, the dicta certainly do not preempt debate on the issue.

Appelbaum (8), writing before the *Burch* decision, concluded that need-for-treatment criteria were not inherently unconstitutional; rather, the statutes struck down by state and federal district courts had been impermissibly vague and/or overly broad. The situation is similar legally to the Supreme Court's rulings striking down state death penalty statutes in the early 1970s; the Court did *not* rule that capital punishment was unconstitutional but rather that the existing statutes were too vague (9). When more tightly drafted statutes were passed, the Court upheld them (10). A similar process may well occur in the case of civil commitment criteria based on need for treatment.

Over the past decade, following the failure of deinstitutionalization, there has been growing criticism of the dangerousness standard as inadequate to deal with the problems of the chronically mentally ill in the community. Critics have pointed out not only that the criterion of dangerousness selects the wrong types of patients (11) but that restrictive civil commitment criteria (12-14) and economic pressures (15) have led to diversion of mentally disordered persons from the civil to the criminal justice system, where they receive even less care than they did in the civil hospitals from which they were "decarcerated" (16) and are thus released back to the streets in the same condition in which they were arrested.

On the basis of a need-for-treatment model first proposed by Stone (17) and subsequently developed by Roth (18), APA accepted as its official policy some guidelines for statutes governing involuntary hospitalization that provided for commitment based on need for treatment under a guardianship model carefully constructed to prevent the abuses of the previous vague statutes struck down in the 1970s (19). Need for treatment is considered necessary, but not sufficient, for hospitalization. The APA model statute permits commitment either according to the usual criteria of danger to self or others or to prevent substantial physical or mental deterioration. There is also a requirement that the patient be incapable of consenting to either hospitalization or treatment.

The proposed statute drew criticism from libertarians (20) and support from some patient advocacy groups (21) and clinicians (22, 23), but the debate continued to be theoretical and ideological rather than empirically based. Opponents of need-for-treatment criteria feared that the clock would be turned back to the days of unfettered clinical decision making, when more than half a million patients were hospitalized involuntarily. To attempt to answer the question of the impact of need-for-treatment criteria, two research groups tried to estimate those effects by asking emergency room clinicians responsible for commitment evaluations according to existing dangerousness criteria to evaluate the same patients simultaneously according to the APA criteria (24-26). They reported that only 36%-56% of patients committable according to the dangerousness criteria would have been committable according to the need-for-treatment criteria, whereas the great majority of patients committable according to the need-for-treat-

ment criteria would also have been committable according to the dangerousness criteria. Such studies cannot, of course, substitute for empirical research into actual changes in admission patterns following changes in commitment criteria.

While no state has adopted the APA criteria in toto, a number of states have changed their statutes to permit commitment in order to prevent other than purely physical deterioration. After a highly publicized double murder by a mentally ill person who had been refused voluntary admission to a state psychiatric facility, the Washington state legislature revised its standard for the gravely disabled to permit commitment of a mentally ill person who "manifests severe deterioration in routine functioning as evidenced by repeated and escalating loss of cognitive or volitional control over his or her actions and is not receiving such care as is essential for his or her health or safety" (27). Following this "horror story" there was nearly a doubling in state hospital admissions over the period of a year, beginning several months *before* the statute went into effect. The increase was attributed by Durham and various colleagues, in a series of articles, chiefly to the broadening of the commitment criteria (28). Their conclusion has been cited again and again when legislatures in other states have considered need-for-treatment criteria, while little has been published concerning even broader criteria in a number of other states.

After the previous need-for-treatment criteria were replaced by dangerousness standards, there were published studies that documented changes in admissions and census at state mental hospitals. With the exception of the Durham articles, there have been no attempts in the psychiatric literature to investigate changes following the reintroduction of need-for-treatment criteria for commitment. This article reports gross data from eight other states.

RESULTS OF CHANGES TO NEED-FOR-TREATMENT CRITERIA

There have in fact been significant changes in commitment statutes in a number of states besides Washington over the past 16 years. Table 1 shows state hospital admissions in these states before and after changes in their statutes. Since different states provided different types of information, total admissions are reported for four states and involuntary admissions for the remaining three.

In 1975 South Carolina passed a statute providing for commitment of patients who need hospital treatment and because of their condition lack sufficient insight or capacity to make responsible decisions with respect to their admission to a hospital (29). While involuntary admissions rose 14% in the year after the changes (table 1), voluntary admissions rose 51% during the same year, indicating that factors other than the new statutory criteria were the major reasons for a rise in admissions.

TABLE 1. State Hospital Admissions After Statutory Changes in Criteria for Involuntary Civil Commitment^a

^aData were supplied by an official of each state's mental health department.

^bInvoluntary admissions.

^cAll admissions.

North Carolina revised its statutes in 1981 to permit hospitalization of persons who are unable to care for themselves, as sufficiently demonstrated by their engaging in grossly emotional or inappropriate behavior or displaying other signs of severely impaired insight and judgment (30). Following the change, both admissions and average census at the state's four mental hospitals, which receive approximately 80% of involuntary admissions, actually decreased. The data on North Carolina in table 1 demonstrate consistent decreases in admissions following the broadening of the commitment criteria.

In addition to the changes in criteria for involuntary hospitalization, North Carolina broadened its criteria for initial commitment to outpatient treatment. This was done to permit commitment of a person who is capable of surviving in the community but (on the basis of previous history) needs treatment to prevent further disability or deterioration that would predictably result in dangerousness and whose mental status negates his or her ability to make an informed decision to seek or comply with recommended treatment (31). The state provided capitation grants of \$2,000 per patient to community mental health centers to encourage the use of the new provision. Despite the broader criteria and financial incentives, Hiday and Scheid-Cook (32) reported that only 8.3% of initial commitments were to outpatient treatment.

Alaska revised its statutes, effective in 1985, to provide for hospitalization of a person who, as a result of mental illness, will, if not treated, suffer distress that impairs judgment, reason, or behavior, causing a substantial deterioration of the person's ability to function independently (33). There had been a mild (8%) rise in admissions to the state mental hospital the year before the changes, but after the changes, admissions fell consistently (table 1).

Hawaii revised its statutes in 1986 to provide for commitment of persons who are "obviously ill," defined as a "condition in which a person's current behavior and previous history of mental illness, if known, indicate a disabling mental illness, and the person is incapable of understanding that there are serious and

highly probable risks to health and safety involved in refusing treatment" (34). There was a significant rise in both new admissions and readmissions (table 1); however, the new statutory provisions have rarely been used because of constitutional questions.

Kansas also revised its statutes in 1986, to provide for commitment of patients who suffer severe mental disorders to the extent that they need treatment, lack the capacity to make informed decisions concerning treatment, and are likely to cause harm to themselves or others. "Likely to cause harm" means that the person is "likely, in the reasonably foreseeable future, to cause substantial physical injury or abuse to self or others, or substantial damage to another's property, as evidenced by behavior causing, attempting or threatening such injury, abuse or damage; or is substantially unable to provide for all of the person's basic needs, such as food, clothing, shelter, health or safety, causing substantial deterioration of the person's ability to function on the person's own" (35). After a rise in admissions before the changes in the statutes, both admissions and census fell after the changes (table 1).

Texas revised its statutes in 1987 to provide for hospitalization of persons who, as a result of mental illness, will, if not treated, continue to suffer severe and abnormal mental, emotional, or physical distress, will continue to experience deterioration of ability to function independently, and are unable to make rational and informed decisions about whether to submit to treatment (36). There was an 8% rise in involuntary admissions the year before the changes, which subsequently leveled out (table 1). Voluntary admissions did not fall after the new statute went into effect.

Colorado revised its statutes in 1989 to provide for hospitalization of persons who suffer from chronic mental disorders with psychotic features, who have been hospitalized at least twice within the previous 36 months, and who exhibit a deteriorating course (37). There was a rise in admissions the year before the changes, with a fall in the year after the changes (table 1).

Arizona passed a statute in 1990 that provides for commitment of persons who suffer from "permanent or acute disability" (38). The constitutionality of this stat-

ute has been challenged. A state court of appeals ruled in 1991 that the statute is not too broad because it requires the clear and convincing showing of a severe mental disorder that has a substantial probability of causing severe mental, emotional, or physical harm; it is not too vague because no warning is required for those incompetent to make treatment decisions and because courts are required to make factual findings of a mental disorder with a substantial probability of causing serious injury (39). The ruling was not appealed to the state Supreme Court, but another challenge is currently before a different appeals court. The new provision has been rarely used because many continue to fear that the criterion is unconstitutional. In the 12 months before the new law went into effect, there were 441 involuntary civil admissions to the Arizona State Hospital, while in the subsequent 8 1/2 months, there were 423. If it is found that this trend continued for the rest of the 12-month period, it would represent a 35% increase in admissions; however, patients committed under the new provision do not make up a significant percentage of the new admissions (personal communication, Dr. J. Migliaro, Arizona State Hospital).

DISCUSSION

Since need-for-treatment criteria have been proposed by APA, and passed by the states I have listed, as additions to existing dangerousness criteria rather than as replacements, some initial increase in admissions after passage of such legislation would certainly be expected. After all, if no new patients were to be admitted, there would be no purpose for the legislation. Proponents of need-for-treatment criteria argue that since a major goal of the legislation is to permit early intervention and to provide effective treatment *before* patients deteriorate sufficiently to satisfy the dangerousness requirements, many of the patients committed under this standard would be committed eventually under existing criteria, and at that time they would require more lengthy hospitalization because of the increased severity of their condition.

With the exception of Washington State, the dire predictions by critics of need-for-treatment standards have not been borne out in practice since the passage of such legislation, despite the fact that no state has yet incorporated the protections proposed by APA in its model statute. This fact illustrates the multidetermined nature of admissions to psychiatric facilities (40).

Broader statutory criteria for commitment are most frequently enacted in a jurisdiction in response to specific circumstances that appear to call for a lower commitment threshold, such as publicized horror stories involving mental patients. In such situations, it is not uncommon for commitment rates to rise even without statutory changes (41), as in fact happened in the state of Washington, as well as in Alaska, Kansas, Texas, and Colorado in the year before their broadened criteria went into effect. Therefore, any observed increases

in commitments may be due as much to the social pressures leading to statutory changes as to the changes themselves.

North Carolina, Alaska, Kansas, Texas, and Colorado passed need-for-treatment criteria for commitment, and all experienced decreases in admissions. In Hawaii and Arizona, rates of admission to state hospitals rose contemporaneously with passage of broader commitment criteria, although data from those state hospitals indicated that very few commitments were made under the new criteria, again supporting the conclusion that both changes in commitment laws and rises in admissions may be due to the same underlying social pressures, rather than the conclusion that broadening the commitment criteria was responsible for the rises in admissions. The moderate rise in involuntary admissions following statutory changes in South Carolina was far overshadowed by an almost fourfold greater concurrent increase in voluntary admissions, which could not be attributed to statutory changes.

From the data presented here, it appears that opposition to broadening commitment criteria on the grounds that existing psychiatric facilities would be overwhelmed (as has been argued recently in the debate in the Wisconsin legislature) is misplaced. Concern about the use of costly inpatient resources, often at the expense of funding for community treatment programs, is certainly appropriate; but such concern should be raised on the basis of any social pressure for increased protection from the mentally ill, not just when statutory changes are proposed. In fact, the proposals themselves may be the best indication of such social pressure. And long-term effects need to be taken into consideration; if the goals of early intervention are realized, there should ultimately be a lowering of hospital census figures because of shorter stays.

It also appears that no broadening of commitment criteria should be enacted without specific attention to the resources that might be required for providing treatment. This was not done in Washington (even with the evidence of significant increases in admissions before the statute went into effect) and caused severe problems in service delivery at one state psychiatric hospital. In contrast, by proactively providing additional funding to outpatient facilities, North Carolina successfully anticipated potential problems stemming from passage of its broader outpatient commitment criteria.

Changes in admission and census rates are multidetermined (15, 40) and cannot be simplistically attributed to a single cause, such as changes in commitment criteria. Detailed studies are required, using interviews with knowledgeable persons involved in implementing changes and reviews of clinical and commitment documents, as well as before-and-after admissions and census data. In addition, such studies should be correlated with current events (as is routine practice in individual psychiatric interviews), and data from one jurisdiction should not be automatically accepted as applicable to another until differences in existing administrative and fiscal policies are factored in. When such comprehen-

sive projections are available, they should serve to provide decision makers with relevant information upon which to base their decisions concerning proposed statutory changes.

The Influence of Topography on the Cognitive and Psychopathological Effects of Tardive Dyskinesia

Keith W. Brown, M.B.Ch.B., and Thomas White, M.B.Ch.B.

Objective: The purpose of the study was to investigate the influence of the topography of dyskinesic movements on their effect on cognitive impairment and negative symptoms. **Method:** Eighty-four inpatients who satisfied DSM-III-R criteria for schizophrenia were rated for tardive dyskinesia, akathisia, and drug-induced parkinsonism, as well as negative symptoms, with the Scale for the Assessment of Negative Symptoms and for cognitive state with the Mini-Mental State examination. The subjects were then divided into those without tardive dyskinesia (N=45), those with orofacial dyskinesia (N=19), and those with limb-truncal dyskinesia (N=20). Differences among the groups were assessed with multiple analysis of covariance (MANCOVA), with age, akathisia, and drug-induced parkinsonism ratings as the covariates. Post hoc Spjotvoll and Stoline tests were then undertaken. **Results:** MANCOVA revealed a significant difference among the groups. Post hoc tests showed that the group with limb-truncal dyskinesia had significantly lower scores on the Mini-Mental State Examination and higher scores on the Scale for the Assessment of Negative Symptoms. The group with orofacial dyskinesia was significantly different from the nondyskinetic group only on the total score for the Scale for the Assessment of Negative Symptoms and the attention subscale. There were no significant differences between the dyskinetic groups. **Conclusions:** After correction for the important confounding variables of age, akathisia, and drug-induced parkinsonism scores, those with limb-truncal and, to a lesser degree, orofacial dyskinesia differed significantly from nondyskinetic comparison subjects in ratings of cognitive impairment and negative symptoms.

(Am J Psychiatry 1992; 149:1385-1389)

Tardive dyskinesia is one of the most serious consequences of exposure to antipsychotic medication, whose importance rests with its potentially irreversible nature. Tardive dyskinesia may affect most areas of the body. Thus, in addition to the classical linguobuccal masticatory movements, there may be choreiform movements of the arms, legs, and trunk. It has been suggested that this limb-truncal dyskinesia can be usefully separated from orofacial tardive dyskinesia and may differ in its pathophysiology, pharmacotherapy, and cognitive sequelae.

There is, however, little agreement in the literature on the differential effects of orofacial and limb-truncal tardive dyskinesia on negative symptoms and cognition.

Received June 12, 1991; revision received March 16, 1992; accepted April 17, 1992. From the Royal Edinburgh Hospital, Edinburgh, and Parkhead Hospital, Glasgow, Scotland, UK. Address reprint requests to Dr. Brown, Bellsdyke Hospital, Larbert, Central Region, Scotland, UK.

The authors thank Dr. Linda Watt and other consultant staff for access to their patients.

Waddington et al. (1) found an association between these variables only with orofacial tardive dyskinesia. Some studies report only orofacial dyskinesia scores (2), while others report dyskinesia scores without reference to the topography of the dyskinesia (3-5). Others have found a relationship between limb-truncal, but not orofacial, tardive dyskinesia and negative symptoms and cognitive impairment (6, 7).

There may be several reasons for these discrepancies. Most of the studies reporting negative results have been conducted on younger patients, in whom the pathophysiology of tardive dyskinesia may differ (8). The prevalence of limb-truncal dyskinesia is higher in younger age groups (9). Studies with a wide age range may thus show an association between orofacial, but not limb-truncal, tardive dyskinesia and cognitive impairment, resulting from the differences in age structure between the dyskinetic subtypes.

Some studies failed to control for the presence of anticholinergic medication, which may have had an adverse effect on cognition. Other movement disorders may be important confounding variables. Thus, both

drug-induced parkinsonism and akathisia may coexist with tardive dyskinesia and may also be associated with negative symptoms or cognitive impairment (6, 10, 11).

In this study, we sought to investigate the relationship between both orofacial and limb-truncal dyskinesia and the severity of cognitive impairment and negative symptoms. Age, drug-induced parkinsonism, and akathisia served as covariates.

METHOD

All the residents of several long-term wards at a hospital were screened. For inclusion the patients had to satisfy *DSM-III-R* criteria for chronic schizophrenia, have at least 5 years' cumulative exposure to antipsychotic medication, be cooperative, and be able to give verbal informed consent to assessment. A change in medication in the preceding month, muteness, established neurological disease, a history of significant alcohol abuse, and known intellectual impairment led to exclusion. Because of incomplete case records, we were unable to calculate total lifetime exposure to antipsychotic medication. Current antipsychotic medication dose was calculated in chlorpromazine equivalents (12).

Eighty-four patients satisfied the criteria. They were seen on two occasions, usually 1 week apart, by the two investigators. They were subsequently reviewed 3 months to 2 years later. Only 19 subjects were shared with a previous study (6). Tardive dyskinesia was assessed by the Abnormal Involuntary Movement Scale (AIMS) (13). Because dyskinetic movements can be modified by anxiety and voluntarily inhibited, part of the assessment was performed unknown to the patients while they attempted to memorize a picture for 2 minutes. Tardive dyskinesia was recorded as present in those who satisfied the criteria of Schooler and Kane (14). All dyskinetic subjects would have been classified as "persistent tardive dyskinesia, concurrent neuroleptics" by these criteria.

Akathisia was rated on a scale developed for this purpose (15). Because few subjects had subjective symptoms of restlessness, evidence of particular patterns of objective restlessness, which have been described as be-

ing most discriminating for akathisia, was required. These included an inability to sit still, rocking from foot to foot for more than half the time while standing, fidgety leg movements while lying or sitting, and an inability to stand without walking or pacing (16). Parkinsonism was assessed on the 10-item scale of Simpson and Angus (17). The patients were rated on the Scale for the Assessment of Negative Symptoms (18), the Hamilton Rating Scale for Depression (19), and the Mini-Mental State examination (20).

The subjects were then divided into three groups: those without tardive dyskinesia, those with orofacial tardive dyskinesia, and those who scored more than 2 on any of the limb-truncal components of the AIMS. Thus, this division was hierarchical, with limb-truncal movements taking precedence over orofacial movements.

Differences between these three groups in demographic and treatment variables were assessed by one-way analysis of variance. The cognitive and negative symptom variables were investigated by one-way multiple analysis of covariance (MANCOVA), in which age, drug-induced parkinsonism, and akathisia scores served as the covariates, and by chi-square tests with Yates's correction when appropriate for dichotomous variables.

RESULTS

The demographic and treatment variables are shown in table 1. There were modest differences between the groups in age and length of hospitalization. There were significant differences between the groups in drug-induced parkinsonism and akathisia ratings. Limb-truncal dyskinetic movements were found in 24% of the patients. This rate is higher than that reported in some (21, 22) but not all (23) studies. The limb-truncal and orofacial groups did not differ in total AIMS scores (mean=10.3, SD=4.9, versus mean=12.5, SD=7.4) or in the global severity score (mean=2.9, SD=0.6, versus mean=3.1, SD=0.4).

There were significant differences between the three groups on MANCOVA (Wilks's lambda=0.71, p=0.02). Post hoc Spjotvoll and Stoline (24) tests were then per-

formed, and the results are shown in table 2. This revealed a consistent difference between the limb-truncal and comparison groups only, with the limb-truncal group being more cognitively impaired and scoring higher on the Scale for the Assessment of Negative Symptoms total and all of the subscales. The orofacial dyskinesia group differed significantly from the non-dyskinetic group only in scores on the Scale for the Assessment of Negative Symptoms total and attention subscale.

We wished to investigate whether the "limb" or "trunk" component of the limb-truncal score had different associations with the cognitive and psychopathological variables. Within the dyskinetic subjects, both the lower limb (Spearman's $r = -0.34$, $df = 47$, $p < 0.05$) and trunk ($r_s = -0.35$, $df = 47$, $p < 0.05$) AIMS scores were significantly negatively correlated with the Mini-Mental State examination score. Similarly, both the lower limb ($r_s = 0.39$, $df = 47$, $p < 0.02$) and trunk ($r_s = 0.43$, $df = 47$, $p < 0.01$) scores had significant positive correlations with the total score on the Scale for the Assessment of Negative Symptoms.

DISCUSSION

After correction for age, drug-induced parkinsonism, and akathisia, limb-truncal tardive dyskinesia was found to be associated with greater cognitive impairment and more severe negative symptoms than was orofacial dyskinesia.

One obvious difficulty with this study lies in the problem of separating the different movement disorders. This is especially difficult with limb-truncal dyskinesia and pseudoakathisia. It is possible that pseudoakathisis movements were erroneously ascribed to limb-truncal dyskinesia. There is not a rich literature on the psychopathological correlates of pseudoakathisia, but one report has found an association with negative symptoms (10). This relationship may, therefore, confound any possible association between limb-truncal movements and negative symptoms.

We chose to tackle this problem in several ways. We used as signs of akathisia patterns of abnormal move-

ments that have been suggested to be discriminating for this condition (16). Despite this, there remained a significant correlation between the akathisia and limb-truncal scores ($r_s = 0.33$, $df = 83$, $p = 0.002$). Thus, the akathisia score accounted for approximately 10% of the variance of the limb-truncal score. Therefore, in the analysis, we used the akathisia score as a covariate to try to minimize its impact as a confounding variable.

The hierarchical nature of the classification of dyskinetic status may cause problems. This approach had to be adopted because very few ($N = 4$) subjects had purely limb-truncal dyskinesia. Thus, the orofacial group had little or no limb-truncal movements, but most ($N = 16$) of the limb-truncal group had orofacial movements. It could, therefore, be argued that our findings merely reflected a relationship with the total severity of dyskinesia, rather than showing any topographic specificity. However, the orofacial and limb-truncal groups did not differ significantly on either total AIMS score or global severity scores.

All of the subjects were currently receiving antipsychotic drugs. It would, however, have been neither practicable nor ethical to withdraw this medication. This raises the possibility that some subjects may have received an erroneous dyskinetic classification. Thus, following recent increases in medication, dyskinetic movements may have been masked. Similarly, those subjects whose antipsychotic medication had been recently reduced may have exhibited a withdrawal dyskinesia. All subjects were, therefore, required to have had no drug changes in the preceding month. This requirement was easily met; only five had had changes within 3 months, and 52 had had no alterations in the preceding year.

Neither the akathisia scoring nor the rating of the Scale for the Assessment of Negative Symptoms scores was undertaken in a manner that was blind to the patients' dyskinetic status. This would, however, have been impracticable because of the overt nature of the dyskinetic movements.

This study was cross-sectional in nature and performed on an atypical group of chronic schizophrenic inpatients. Therefore, extrapolation to other populations has to be undertaken with care.

There is some evidence of caudate pathology in tardive dyskinesia. Caudate abnormalities have been reported in neuropathological (25), pneumoencephalographic (26), CT scan (27), and magnetic resonance imaging scan (28) studies. There is one report that subjects with limb-truncal dyskinesia have a greater degree of caudate atrophy than those with orofacial tardive dyskinesia (29). This finding is in keeping with the suggestion of Lohr and colleagues that limb-truncal dyskinesia may be associated with widespread loss of the numerically common γ -aminobutyric acid-releasing Spiny 1 neurons in the neostriatum (9). They also suggested that damage to the numerically less common cholinergic Spiny 11 cells would result in orofacial dyskinesia, little CT scan evidence of caudate atrophy, and only little cognitive impairment. Consistent also with this,

^dSignificant difference between comparison and limb-truncal dyskinesia groups ($p=0.009$).

^eSignificant difference between comparison and limb-truncal dyskinesia groups ($p=0.0007$).

^fSignificant difference between comparison and orofacial dyskinesia groups ($p=0.03$) and comparison and limb-truncal dyskinesia groups ($p=0.0007$).

Klawans and Rubovits (30) found that cholinergic agents improved orofacial tardive dyskinesia to a much greater degree than limb-truncal dyskinesia.

Mukherjee et al. (29) found that subjects with limb-truncal dyskinesia also had greater frontal blood flow, as assessed by single photon emission computed tomography, than those with orofacial tardive dyskinesia. This may be analogous to the reported greater frontal blood flow in those with Huntington's chorea (31). This may be due to an "outflow obstruction" of the main efferent pathways from the frontal lobes in the caudates (31).

Limb-truncal dyskinesia is important by virtue of its relative frequency and the severity of its cognitive and psychopathological sequelae. Its study appears to have been adumbrated by that of orofacial dyskinesia. This is despite the early comment of Delay and Deniker that orofacial dyskinesia was the "most common and least worrying" movement syndrome. However, they also noted that "choreic movements of the limbs are very variable and difficult to classify" (32). Although it is difficult to assess, we would conclude that limb-truncal dyskinesia merits further study.

The Impact of Antipsychotic Drug Regulations on Psychotropic Prescribing Practices in Nursing Homes

Barry W. Rovner, M.D., Barry A. Edelman, B.S.Pharm.,
Melanie P. Cox, R.N., M.S., and Yochi Shmuely, M.S.W.

The authors prospectively studied psychotropic prescribing practices and quality assurance data in 17 nursing homes in the Baltimore area to assess the impact of federal antipsychotic drug regulations. There was a 36% reduction in prescriptions for neuroleptics over 6 months, no increase in prescriptions for sedative/hypnotics, and a small increase in prescriptions for antidepressants. The authors conclude that psychotropic drug prescribing practices and patient outcomes remain important areas of study in nursing homes.

(Am J Psychiatry 1992; 149:1390-1392)

Neuroleptic drugs are frequently prescribed in nursing homes, and the particular ones used are often not optimal for elderly patients (1, 2). In a recent study of 454 nursing home patients (3), we found that 34% of patients who had dementia without delusions or hallucinations received neuroleptics, as did 24.1% of primarily depressed patients without dementia and 6.7% of patients with no psychiatric diagnosis at all.

Recognition of the data on use of neuroleptic drugs and recommendations from the Institute of Medicine resulted in federal legislation restricting the use of neuroleptics and restraints in nursing homes (the Omnibus Reconciliation Act, or OBRA, of 1987), which went into effect in October 1990. Prescribing a neuroleptic now requires specific diagnoses and behavioral indications. Garrard et al. (4) found that had OBRA regula-

tions been in effect from 1976 to 1985, 50% of neuroleptic use in almost 9,000 nursing home patients would have been out of compliance.

The impact of the new regulations has not yet been assessed. Whether they will result in less neuroleptic use or more use of other psychotropic medications or physical restraints is not known. For this study we evaluated psychotropic drug prescribing practices longitudinally for the 3 months before and the 3 months after October 1990, when the regulations went into effect, in 17 community nursing homes in Maryland. Over this time period, a pharmacist-sponsored education program for physicians and nurses was implemented. We also evaluated changes in use of restraints and in nursing home quality assurance reports to estimate possible clinical consequences.

METHOD

All 17 Baltimore-area nursing homes owned by Meridian Healthcare participated in the study. They were licensed as intermediate/skilled care facilities and ranged in size from 104 to 250 beds. Patients were admitted from the mainly white (81%-84%) and middle-income communities surrounding each home. There were 2,709 patients in the 17 homes.

Computerized monthly pharmacy reports were reviewed from July to December 1990 to determine the

FIGURE 1. Use of Psychotropic Drugs (N=2,707) and Restraints (N=1,923) for Residents of 17 Nursing Homes in July–December 1990

proportion of patients for whom all neuroleptics, benzodiazepines, antidepressants, or barbiturates were prescribed. To determine whether the patients who received neuroleptics throughout the study period had dose changes, only prescriptions of haloperidol and thioridazine were reviewed. These two neuroleptics were considered representative of others because they are most often prescribed in nursing homes (4). Nursing quality assurance data for 12 of the 17 nursing homes, involving 1,963 patients, were reviewed and included information on use of restraints, bedsores, weight loss (3–5 lb/30 days), falls with fractures, adverse incidents such as falls without injuries, urinary tract infections, and deaths. Five of the 17 homes were unable to provide these data, but they did not differ from the other homes in other respects.

To test for the significance of changes over time, a normal-deviate or *z* test for linear trends in proportions was used (5). To test for differences in restraint use, a *t* test was used.

In January 1990 the Meridian pharmacy service mailed the OBRA regulations to all medical directors, primary care physicians, and directors of nursing. In May 1990 all 17 nursing homes completed an assessment form recording indications for restraint and neuroleptic use, their potential side effects, and the required physician evaluations. In July 1990, the pharmacy service sponsored in-service education for nurses and physicians on proper indications, recognition of side effects, and appropriate documentation of these treatments. The pharmacy service subsequently reviewed medical records and determined whether appropriate indications were recorded. In September 1990, pharmacists asked physicians to reevaluate patients who were receiving neuroleptics or restraints without appropriate documentation.

TABLE 1. Prevalence of Medical Events Among 1,923 Residents of 17 Nursing Homes in July and December 1990

Medical Event	Period Prevalence (%)		z	p
	July	December		
Bedsores	4.8	3.3	-3.33	<0.0005
Weight loss	4.0	3.2	-1.87	n.s
Falls with fractures	0.2	0.4	1.28	n.s
Adverse incidents	12.0	14.0	3.75	<0.0001
Urinary tract infections	3.2	4.0	2.18	<0.05
Deaths	0.7	1.1	1.95	<0.05

RESULTS

Complete demographic and medical data on the 2,707 patients were unavailable; however, we studied a subgroup of patients in eight of the homes (N=454) (3) and found them to be comparable to patients in the 1985 National Nursing Home Survey (6).

In July 1990, 15.4%–45.0% (mean=25.4%, SD=7.2%) of patients in the 17 homes received neuroleptics. Figure 1 shows the use of psychotropic drugs and restraints by month in July–December 1990. Over this interval there was a marked overall decrease in prescriptions of neuroleptics from 25.4% to 15.9% ($z=-9.72$, $p<0.0001$). The magnitude of the decrease ranged in the 17 nursing homes from 9.9% to 65.6% (mean=36.1%, SD=19%) but was unrelated to the July 1990 rates ($r=0.36$, $df=20$, $p=0.16$). For patients who received haloperidol or thioridazine throughout the study period (N=135), 71 (52.6%) had no change in dose, 52 (38.5%) had their doses reduced, and 12 (8.9%) had their doses increased. There was a slight increase in prescriptions of antidepressants from 19.4% to 21.9% ($z=3.68$, $p<0.001$), a decrease in prescriptions of benzodiazepines from 15.4% to 11.9% ($z=-4.02$, $p<0.001$), and a slight change in prescriptions of barbiturates from 2.0% to 2.3% ($z=0.87$, n.s.). The proportion of patients for whom restraints were prescribed decreased from 33.6% (range=12%–73%) in July 1990 to 15.7% (range=5%–25%) in December 1990, a 53.3% reduction ($t=5.39$, $df=9$, $p<0.0001$).

Table 1 shows the prevalence of medical events reported in quality assurance reports in July and December 1990. There was a slight decrease in bedsores and slight increases in adverse incidents, urinary tract infections, and deaths. There were no changes in weight loss or falls with fractures.

Psychotropic drug use was reassessed in October 1991. The proportion of patients receiving neuroleptics was 13.5%, antidepressants 18.6%, benzodiazepines 14.7%, and barbiturates 2.0%.

DISCUSSION

We prospectively studied psychotropic prescribing practices in a large sample of community nursing home patients in Maryland. The characteristics of the patients

and the homes were similar to other for-profit community nursing homes in the United States (3). The corporation that owns the homes developed an active pharmacy program to meet the new federal antipsychotic drug and restraint regulations. This included in-service education for nurses and physicians and notifying physicians of drug and restraint regimens potentially out of compliance.

We found considerable reductions in neuroleptic use over the 6-month study period, no increase in use of sedatives/hypnotics, and a slight increase in use of antidepressants. One year later, the lower level of neuroleptic use was sustained and no increases in other psychotropics were observed. The maintenance of a lower level of neuroleptic use is probably attributable to the ongoing requirement that physicians complete an "indications and side effects" document for all residents receiving these drugs. There were also substantial reductions in the use of physical restraints for similar reasons. The initial increase in use of antidepressants was not sustained 1 year later and likely represented expected monthly variation rather than increased treatment of depression.

Although small but significant changes were noted in the quality assurance reports we reviewed, they are difficult to interpret because comparable data from previous years are unavailable. Nevertheless, they suggest that no major deviations occurred.

This study suggests the effectiveness of a pharmacy-sponsored physician and nurse education program to meet OBRA drug and restraint regulations. Previous studies have demonstrated similar successes using educational

outreach and physician feedback, although other factors (e.g., publication of OBRA requirements in the medical literature and other physician communications) may contribute (7, 8). Taken together, these studies encourage future interventions of this kind to reduce unnecessary use of medications. In the meantime, psychotropic prescribing practices and patient outcomes remain important areas of study in nursing homes.

Anticholinergic Effects of Drugs Commonly Prescribed for the Elderly: Potential Means for Assessing Risk of Delirium

Larry Tune, M.D., Suzanne Carr, B.S.,
Elizabeth Hoag, B.S., and Tawnya Cooper, B.A.

Anticholinergic effects of the 25 drugs most commonly prescribed for the elderly were measured by radioreceptor assay. Fourteen had detectable anticholinergic drug levels; 10 of these had levels that have been associated with impairments in memory and attention in normal elderly subjects. These data indicate that patients taking multiple medications may be at increased risk for side effects from psychotropic drugs, most of which have anticholinergic effects.
(Am J Psychiatry 1992; 149:1393-1394)

The systemic absorption of anticholinergic medications is one likely mechanism of drug-induced delirium in the elderly (1-6). Medications with anticholinergic effects are associated with delirium more commonly than is any other drug class (5). Although anticholinergic-related delirium has long been recognized (3), the full extent of this syndrome may not yet be fully appreciated. The anticholinergic effects of many drugs and their metabolites are unknown. Since most elderly patients take three or more drugs (7), many of which have known anticholinergic effects, it is possible that an anticholinergic intoxication syndrome could result from complicated medication regimens in which several medications, some or all of which have modest anticholinergic effects, are prescribed. It is possible that the net risk of anticholinergic toxicity from complicated drug-drug interactions is high, even though the patient receives no readily identifiable anticholinergic compound.

We investigated the anticholinergic effects of the 25 drugs most frequently prescribed for the elderly (8). This is the first study in which these drugs have been investigated in the same assay system and the antimuscarinic effects tabulated. While some of the drugs are typically associated with anticholinergic side effects, others (e.g., warfarin) are not.

METHOD

We obtained from pharmaceutical companies, listed in the *Physicians' Desk Reference*, samples of parent

compounds of the 25 medications most commonly prescribed for elderly patients (according to the Health Care Financing Administration's initial listing of 225 drugs) (8). The anticholinergic effects of a standard concentration (10^{-8} M) of each compound were assessed in an anticholinergic radioreceptor assay (9-12). The details of this antimuscarinic radioreceptor assay have been published elsewhere (2, 10, 11). Each medication was diluted to the 10^{-8} M concentration, and anticholinergic drug levels were compared to an internal standard of atropine sulfate. So that drug levels could be compared using a uniform unit of measure, each level was then expressed as nanograms per milliliter of equivalent amounts of atropine (atropine equivalents).

RESULTS

Table 1 presents the anticholinergic drug level associated with a 10^{-8} M concentration of each compound in the radioreceptor assay (9, 10). Of the 25 most commonly prescribed drugs for the elderly, 14 produced detectable anticholinergic effects. Ten of these (ranitidine, codeine, dipyridamole, warfarin, isosorbide, theophylline, nifedipine, digoxin, Lanoxin, and prednisolone) produced anticholinergic levels that have been shown to cause significant impairments in tests of recent memory and attention in normal elderly control subjects (11).

DISCUSSION

Our results show that many medications commonly prescribed for the elderly have detectable anticholinergic effects and thus may contribute to an anticholinergic intoxication syndrome. While it is known that some compounds have anticholinergic effects, this is the first report identifying the relative anticholinergic effects of commonly prescribed agents in the same assay. Most of

^aAt a 10⁻⁸ M concentration.^bA digoxin compound.

these drugs are not typically identified as anticholinergic, and the net effect of combinations of these drugs is also generally not associated with anticholinergic toxicity. As a means of comparison, in a related study of patients in a nursing home population (12), drug levels in excess of 0.83 ng/ml of atropine equivalents were shown to have a significant effect on the capacity for self-care of elderly, largely demented subjects. The levels we found are likely to underestimate the antimuscarinic effects of these medications in patients, since potentially active metabolites of each parent compound were not assayed.

Clinicians will readily appreciate that many of their elderly patients are prescribed several of these medications simultaneously. This report should serve as a warning to psychiatrists that the addition of any medi-

cation to an already complicated medication regimen, especially that of an elderly patient, carries with it the potential risk of adversely affecting cognition in the patient. This is particularly worrisome when antidepressants or antipsychotic medications with established anticholinergic effects are prescribed. A record of all medications should be carefully obtained, and attention should be given to possible multiple drug interactions. These data may serve to alert the clinician to possible toxic drug combinations. Perhaps, by using alternative drugs, multiple anticholinergic compounds can be avoided. In instances in which an elderly patient is likely to encounter anticholinergic effects of multiple medications, the patient should be examined carefully and often for signs of anticholinergic toxicity.

Comparison of Fluorescent Polarization Immunoassay and Radioimmunoassay in Measuring Cortisol Levels in Prepubertal Depressed Children

Ronald A. Weller, M.D., Shahnour Yaylayan, M.D.,
Elizabeth B. Weller, M.D., and Mary A. Fristad, Ph.D.

Cortisol levels of 21 hospitalized prepubertal depressed children given the dexamethasone suppression test (DST) were measured by radioimmunoassay and by fluorescent polarization immunoassay, a new assay method. Correlation analyses demonstrated a highly significant linear relationship between the two methods of measuring cortisol. Thus, it may be possible to use fluorescent polarization immunoassay to measure cortisol levels in children undergoing the DST.
(Am J Psychiatry 1992; 149:1395-1396)

To perform a dexamethasone suppression test (DST) successfully, it is critical that cortisol levels be measured accurately at low plasma concentrations (1-4). The two most commonly used assay methods for determining plasma or serum cortisol levels have been competitive protein-binding assay and radioimmunoassay.

Ritchie et al. (5) reported that radioimmunoassay was the preferred method because it was easy to perform, highly specific, and low in cost. However, different antibodies may be used in the assay, and the method of separating bound from free steroids varies among laboratories. For these reasons, the results of different commonly used commercial radioimmunoassay kits are not always consistent. The APA Task Force on Laboratory Tests in Psychiatry (6) reported that commercially available radioimmunoassay kits yield inconsistent assay values for the same sample, and the same assay method can be inconsistent over time (5, 7).

The competitive protein-binding assay uses human cortisol-binding globulin as the primary binder for cortisol (5). This method can accurately measure relatively low levels of cortisol with good reliability and sensitivity. However, the competitive protein-binding assay is not completely specific for cortisol. Furthermore, this assay must be performed carefully to obtain adequate accuracy and precision, especially at low concentrations of cortisol (0-10 µg/dl), which are critical for the DST (5).

Recently, a nonisotopic immunoassay for cortisol was introduced. This new assay uses fluorescent polarization immunoassay technology. It is highly sensitive and specific for cortisol. Furthermore, it does not use

radioactive isotopes (8). The purpose of the current study was to compare the new fluorescent polarization immunoassay with the more widely used radioimmunoassay for measuring plasma cortisol levels in prepubertal children undergoing a DST.

METHOD

The subjects were 21 consecutively hospitalized prepubertal children (Tanner stage I), aged 6-12 years, who met the *DSM-III-R* criteria for major depression. There were 16 boys and five girls. All underwent a DST as part of their clinical evaluation. The DST was performed under conditions that have been previously described (9).

Baseline cortisol levels were measured at 8:00 a.m. and 4:00 p.m. At 11:00 p.m. the same day, a 0.5-mg oral dose of dexamethasone was given. Cortisol levels were then measured the next day at 8:00 a.m. and 4:00 p.m.

Serum cortisol levels were determined by means of the split-sample duplicate determination method with both a radioimmunoassay kit (Serono Laboratories, Inc., Braintree, Mass.) and a fully automated fluorescent polarization immunoassay using the Abbott Tdx fluorescence polarization analyzer (Abbott Laboratories, North Chicago). Assays were done individually as they were ordered clinically. Not all subjects had cortisol values from both radioimmunoassay and fluorescent polarization immunoassay at all four time points, as indicated in table 1.

RESULTS

Pearson correlation coefficients were calculated to determine the association between radioimmunoassay and fluorescent polarization immunoassay cortisol val-

TABLE 1. Correlations of Cortisol Values Determined by Radioimmunoassay and by Fluorescent Polarization Immunoassay at Four Time Points for 21 Prepubertal Children Given the DST

Condition and Time of Sampling	Range of Cortisol Values ($\mu\text{g/dl}$)		Analysis		
	By Radioimmunoassay	By Fluorescent Polarization Immunoassay	r	df ^a	p
Predexamethasone					
8:00 a.m.	7.2–22.1	6.8–22.4	0.86	19	<0.0001
4:00 p.m.	2.2–11.9	2.1–17.1	0.92	14	<0.0001
Postdexamethasone					
8:00 a.m.	0.2–14.2	0.5 ^b –12.4	0.98	17	<0.0001
4:00 p.m.	0.4–18.5	0.5 ^b –18.2	0.98	15	<0.0001

^aNot all data points were available for all subjects.

^bLevels reported as <1.0 were recorded as 0.5 for the purpose of statistical calculations.

ues at each of the four time points (table 1). Correlations at each of the four sampling times were highly significant.

To determine whether the degree of correlation between radioimmunoassay and fluorescent polarization immunoassay was in some way affected by cortisol values that were either high or low, cortisol levels were divided into high ($>8 \mu\text{g/dl}$), medium ($\geq 3 \mu\text{g/dl}$ to $\leq 8 \mu\text{g/dl}$), and low ($<3 \mu\text{g/dl}$) categories. Correlations were then calculated for cortisol levels obtained within these categories at each of the four sampling times. This was done to maintain independence of analyses for repeated measures. At least five paired observations were required for statistical analyses; thus, only six of 12 comparisons were analyzed. All correlations were significant (for high cortisol values: 8:00 a.m. baseline, $r=0.81$, $df=18$, $p<0.0001$; 8:00 a.m. postdexamethasone, $r=0.91$, $df=4$, $p<0.03$; for medium values: 4:00 p.m. baseline, $r=0.88$, $df=11$, $p<0.0002$; 4:00 p.m. postdexamethasone, $r=0.92$, $df=5$, $p<0.01$; for low values: 8:00 a.m. postdexamethasone, $r=0.64$, $df=12$, $p<0.02$; 4:00 p.m. postdexamethasone, $r=0.90$, $df=8$, $p<0.001$).

With $5.0 \mu\text{g/dl}$ as the cutoff value for nonsuppression of cortisol, we used chi-square analyses to compare the sensitivities of the radioimmunoassay and the fluorescent polarization immunoassay in interpreting the DST. The results were highly significant ($\chi^2=65.01$, $df=1$, $p<0.0001$), with 71 of 73 cortisol levels in agreement. For 27 levels, both assays indicated a negative DST result (i.e., $<5 \mu\text{g/dl}$). For 44 levels, both assays indicated a positive DST result (i.e., $>5 \mu\text{g/dl}$). Finally, in two instances, the radioimmunoassay levels showed negative results (4.40 and $4.80 \mu\text{g/dl}$) while the fluorescent polarization immunoassay levels showed positive results (5.50 and $5.00 \mu\text{g/dl}$, respectively).

DISCUSSION

In this study, cortisol levels determined by fluorescent polarization immunoassay and by radioimmunoassay were highly correlated. This correlation was consistent at varying absolute cortisol levels. To our knowledge, there are no similar studies of children for comparison. Ritchie et al. (8) compared plasma cortisol levels in 169

postdexamethasone samples by using fluorescent polarization immunoassay and competitive protein binding. Cortisol values determined by the two methods were highly correlated; however, all 62 subjects were adults.

Although preliminary, this study suggests that it may be possible to use fluorescent polarization immunoassay to measure cortisol levels in prepubertal depressed children undergoing a DST. A $5 \mu\text{g/dl}$ cutoff value for the fluorescent polarization immunoassay method provided results comparable to those obtained with the same value for the radioimmunoassay method. However, the question of whether the variability of fluorescent polarization immunoassay is comparable to the interest and interkit variability of radioimmunoassay is left unanswered. Thus, replication and further study are indicated.

Nancy C. Andreasen, M.D., Ph.D., Editor

GENERAL REVIEW

Review of General Psychiatry, 3rd ed., edited by Howard H. Goldman, M.D., M.P.H., Ph.D. Norwalk, Conn., Appleton & Lange, 1992, 481 pp., \$29.50 (paper).

The *Review of General Psychiatry* has become a popular educational tool in courses for medical students. This third edition follows a first (1984) and second (1988). Each chapter has been thoroughly updated without sacrificing the brevity and conciseness the editor promises his readers. Five chapters that are new to this edition include an outstanding one, "Group Psychotherapy" by Nick Kanas, who also contributes the excellent chapter on alcoholism.

The book has four main sections: Theory and Concepts, chapters 1 to 8; Psychiatric Assessment, chapters 9 to 15; Mental Disorders, chapters 16 to 30; and Treatment Modalities, chapters 31 to 43, which includes the topics of behavioral medicine, caring for the chronically ill and dying patient, geriatric psychiatry, consultation-liaison psychiatry, forensic psychiatry, and emergency psychiatry.

There is also a glossary of psychiatric signs and symptoms that is slightly more than four pages in length. It is the one portion of the book where brevity creates a disadvantage, and since it is followed by an unusually complete index of 14 pages it is difficult to understand how the glossary would be of much help to medical students. It might better have been placed with the chapter on the mental status examination because it confines itself to signs and symptoms, but even there it would need reworking to include some of the phenomena considered important enough to be boldfaced in the text, such as coma, somnolence, lethargy, vigilance, comprehension, constructional ability, and abstraction.

The high quality maintained in the rest of the book more than compensates for any lack in the glossary. The authors, almost without exception, have clearly made a special effort to address medical students in language familiar to them. In "Personality Disorders," for example, Charles Marmar considers each disorder as it might appear in medical practice, how it affects treatment and the patient/doctor relationship, and what might be a useful tack to take in approaching a patient with that disorder. In a table of defense mechanisms, David Preven and James David define "sublimation" as redirection of an unacceptable impulse into an acceptable form of behavior: an individual with intense unconscious voyeuristic impulses becomes a sex therapist.

Throughout the book, good use is made of clinical vignettes. Dr. Goldman introduces the section on psychiatric assessment with a two-page character sketch of "The Mayor of Wino Park." He ends the section with an eight-page clinical case summary of the "mayor" that demonstrates how the material in the assessment section is applied to an actual case.

Review of General Psychiatry is a first-rate achievement. It should be welcomed by every instructor of psychiatry in medi-

cal schools and by any psychiatrist who tries to describe the biopsychosocial perspective.

ROBERT J. CAMPBELL, M.D.
New York, N.Y.

PSYCHOPHARMACOLOGY

The Practitioner's Guide to Psychoactive Drugs, 3rd ed., edited by Alan J. Gelenberg, Ellen L. Bassuk, and Stephen C. Schoonover. New York, Plenum, 1991, 504 pp., \$37.50.

This soft-covered text is a meaningful attempt to provide information to the practicing physician about psychoactive drugs. It often gives some background information about psychiatric disorders before discussing the treatment of these disorders. Such information may be especially useful to primary care physicians or medical trainees. The table of contents reveals an ambitious array of topics, including some not always covered in a psychopharmacology text, such as insomnia, use of psychotropics during pregnancy, and pediatric and geriatric psychopharmacology.

The book is multiauthored and has some unevenness in quality. The chapters covering the treatment of major psychiatric disorders such as mood, anxiety, and psychotic disorders are nicely done and present substantial clinical material that is very useful. (Where else can a busy clinician find a list of 11 saliva substitutes for anticholinergic dry mouth?) Contrarily, some chapters seem to lack scientific rigor at times. For example, the discussion of benzodiazepine abuse suggests that tolerance develops to the anxiolytic effects, leading to increases in dose. Although an occasional patient with anxiety disorder may need a slight dose adjustment, there is no good evidence that anxiolytic tolerance develops in most appropriately selected patients with anxiety.

Another occasional problem is that some tables appear to be so overinclusive that they lose their intended usefulness. The table on organic causes of depression lists 66 disorders, including diseases such as brucellosis. (You may want to quiz your colleagues about the possibility of brucellosis in your next febrile depressed patient.) Similarly, table 12 lists many medications that may be "associated" with but not necessarily "causative" of depression. How good are the data that led to placing many of these medications on this list? Without detailed discussion, this information may create more confusion than enlightenment.

The chapter on psychotropic treatment during pregnancy presents a useful review. This chapter and divine guidance can help the physician treat these challenging patients.

The discussion about insomnia covers a topic that concerns many patients and physicians but, unfortunately, not enough researchers. The author suggests that there are conflicting data about whether antihistamines are useful for insomnia. He also states that there is little evidence that over-the-counter hypnotics are more effective than placebo.

This book should be considered by physicians or medical trainees who want a respectable overview of psychotropic medications. It measures 9 by 7 inches, thereby fitting into an extra large white coat pocket. However, its more than 500 pages will give the coat a slight list to starboard.

MICHAEL J. GARVEY, M.D.
Iowa City, Iowa

Manual of Clinical Psychopharmacology, 2nd ed., by Alan F. Schatzberg, M.D., and Jonathan O. Cole, M.D. Washington, D.C., American Psychiatric Press, 1991, 352 pp., \$35.00 (spiral-bound).

One of the defining roles of a psychiatrist is the prescribing of psychotropic drugs. The medical profession and the public expect psychiatrists to be experts in this area. Therefore, it is important for psychiatrists to have a solid base of information on psychopharmacology and to build on this base with clinical experience, discussions with colleagues, and regular doses of self-education through reading journals, newsletters, and books. The problem with books in fulfilling this function is that they are often dry renditions of studies that do not reflect actual clinical practice and challenges. The book under review attempts to avert this problem and "to provide the reader/practitioner with basic and practical information regarding the many classes of psychiatric medications" (p. 3). The authors set out to accomplish this by "drawing on our own clinical experience as well as the scientific literature" and not by recounting "a series of meticulously documented review papers" (p. 3).

The authors succeed in providing a readable, useful review of psychopharmacology for the clinician. The book has a conversational tone and reads as if one were listening to expert colleagues chatting about their current opinions regarding the use of psychotropic drugs. This tone is embedded in clear, logically structured chapters, covering antidepressants, antipsychotics, mood stabilizers, antianxiety agents, hypnotics, and stimulants. In addition, there are chapters on combination treatments, emergency room treatments, and pharmacotherapy of chemical dependence and special situations (pregnancy, geriatric patients, medical conditions, etc.). There is also a chapter on general principles of psychopharmacological treatment (which concentrates mainly on informed consent and Food and Drug Administration issues) and one on the diagnosis and classification of psychiatric disorders that is, however, too superficial for clinicians and probably even residents and should be either expanded or deleted.

An annoying aspect of the book's format is that the authors reference few of their statements, choosing to place an extensive bibliography at the end of each chapter. This is not a problem when the authors clearly label a statement as resulting from their clinical experience, such as, "We have recently become impressed by the number of acutely psychotic patients who show little response to relatively high doses of perphenazine and have been using the drug less often in manic and schizophrenic patients" (p. 101). However, if a reader wishes to pursue a particular statement to its source or wishes to check when or where a study was published or who did it, he or she is faced with attempting to find it in the lengthy bibliography. Sometimes it is not clear if a statement is from the authors' clinical experience or from a study, e.g., "One notable exception [to the rule that antidepressants take 2 weeks to work] is amoxapine, which may work in as little as 4 days and enjoys a claim for more rapid onset" (p. 42) or, "Meprobamate is, in fact, an effective antianxiety agent in the same sense

that diazepam or chlordiazepoxide is effective, although controlled studies directly comparing the efficacy of meprobamate with benzodiazepines are almost nonexistent" (p. 209). The authors are also inconsistent, occasionally referencing a particular statement (although not often) and referencing some tables but not others.

There are several omissions from the book that weaken its general usefulness. In the chapter on hypnotics, there is no discussion of attempting sleep hygiene methods before giving a hypnotic. There is little to no information in the book either noting the lethal doses of medications or describing the symptoms or treatment of overdoses. This is especially surprising given that the authors appropriately advise that psychiatrists should call emergency room physicians when overdoses occur because "emergency room physicians may know less about the pharmacological effects of psychiatric drugs than they [psychiatrists] do" (pp. 289-290). This manual, however, gives no information regarding the management of the overdose itself and would thus not allow the psychiatrist to help out the emergency room physician. Finally, although there is occasional mention in the chapters regarding costs, there is insufficient discussion of the relative costs of psychiatric drugs and the manner in which this should be factored into decisions regarding prescribing. Although there is a table in the appendix listing the price of medications, it is incomplete, leaving out benzodiazepines, hypnotics, mood stabilizing agents, and stimulants.

Overall, this manual's strengths outweigh the relatively minor weaknesses noted. It is written in a clear conversational style by two acknowledged experts in psychopharmacology who are sensitive to the fact that clinicians have to make decisions regarding patients despite an incomplete data base in the scientific literature to support them. These authors give such clinicians clear, up-to-date, and rational guidelines on how to proceed given this ambiguity by reviewing the available literature and conveying the knowledge they have gained through their extensive clinical experience. Absorbing the contents of this book will allow clinicians to develop the expertise in psychopharmacology expected of them by their medical peers and the public.

BARRY LISKOW, M.D.
Columbus, Ohio

What You Need to Know About Psychiatric Drugs, by Stuart C. Yudofsky, M.D., Robert E. Hales, M.D., and Tom Ferguson, M.D. Washington, D.C., American Psychiatric Press, and New York, Grove Weidenfeld, 1991, 619 pp., \$35.00.

Consumers have been legitimately concerned about the possible hazards of medication, and it seems that, of late, increasing concern has been expressed about psychiatric drugs. Articles in magazines and newspapers regarding Prozac (fluoxetine) and Halcion (triazolam), for example, assault the consumer and patient with the potential horrors of psychiatric medication. Members of the antipsychiatric establishment commonly accuse psychotropic drugs of producing both long-term and short-term damage. However, there is relatively little objective information available to consumers and patients, outside of standard home medical care guides and the psychiatric drug guide published by Consumers Union. It is fitting, then, that the American Psychiatric Press published this book for the psychiatric patient regarding the drugs that form the basis of psychiatric practice.

What You Need to Know About Psychiatric Drugs admirably provides clear and accessible information about psychotropic drugs for a patient. It begins with a series of prototypical questions that a patient might ask regarding the use of psychotropic drugs and how these questions might be answered. The first half of the book then reviews drugs by their therapeutic classification. The first chapter, on antidepressant drugs, sets the model for the remainder of this section of the book. There is a very clear definition of depression and depressive symptoms, illustrated by several paragraph-long case histories of patients with the disorder. Each chapter describes the clinical use of a particular class of psychotropic drugs: antidepressants, anti-anxiety drugs, anti-panic and anti-phobic drugs, anti-manic drugs, antipsychotics, sedatives and sleeping pills, anti-addiction drugs, and drugs for attention-deficit hyperactivity disorder. Each also contains important sections about drugs that do *not* treat depression and should not be used for depression. Information on overdose and drug interactions is clearly provided. The first half concludes with chapters on drugs for dementia, for the elderly, and for anger and aggression, a chapter on ECT, and an optimistic chapter outlining the development of psychiatric drugs and treatments for the future. The writing is very clear, nonpatronizing, and designed to be accessible and helpful to the lay reader. The content is accurate, although in a few cases the lag between the writing of the book and the publication makes a few statements out of date (e.g., fluoxetine is no longer available only in 20-mg tablets but also in liquid form).

The second half of the book lists individual drugs in alphabetical order. Each drug receives 3–4 pages, and each chapter is organized similarly. The generic and brand names are given, and cross-references to drugs mentioned elsewhere in the are provided. Next, a paragraph of “fast facts” tells the reader to which class the drug belongs, whether a prescription is needed, whether it is available as a generic, and whether it is habit forming. A big white cross on a black background visually calls attention to the possibility of overdose.

Special precautions are then discussed, such as pregnancy and breast feeding, infants and children, the elderly, and driving. Reasons for not taking the medication are also given. Next, a list of benefits versus risks, prescribing guidelines, and a list of interactions with other drugs, foods, and alcohol are provided. Nondrug alternative treatments discussed elsewhere in this book are referred to, and a brief description of long-term use is provided.

In these individual drug description sections, which are generally superb, occasional information may raise questions. For example, regarding dosage of triazolam, the authors say, “A maximum daily dose of up to 0.5 mg/night may be used, if necessary.” Although this is theoretically true, some readers may interpret this as license to take 0.5 mg, when current information clearly suggests that this dose is too high except under very unusual circumstances. The habit-forming potential of triazolam is listed as high, but the risk of becoming dependent on triazolam is not discussed or placed in a risk-versus-benefit context (nor is this discussed for other benzodiazepines). It is possible, therefore, that this information might frighten some readers away from benzodiazepines or even triazolam without their clearly understanding that short-term use does not necessarily lead to dependence and that dependence, although likely after prolonged use, still, in most cases, may be mild and reversible. With fluoxetine, the other drug of current concern, one of the more common side effects (sexual dysfunction) is not mentioned, and, as already noted, the possibility of a dose less than 20 mg is not discussed.

Overall, in a large and comprehensive book such as this one,

various readers may find other small matters to quibble with, but the benefits of the book must clearly be trumpeted louder. My expectation is that this exceptionally clearly written and comprehensive volume will be very useful to patients who have concern about the drugs they may be taking or considering. It certainly is a resource for psychiatrists whose patients may ask, “What can I read about my disorder or the medication that I am taking?” For the patient who wishes to be informed, this book should have the very highest recommendation. My only concern is that, since it is written by psychiatrists and published by the American Psychiatric Press, it may be seen as self-serving by those who will look for any excuse to attack psychiatry or psychiatric medication. I hope, therefore, that the book will be distributed widely enough to be reviewed and seen by enough informed readers that its importance and usefulness will become widely known.

CARL SALZMAN, M.D.
Boston, Mass.

Child and Adolescent Clinical Psychopharmacology, by Wayne H. Green, M.D. Baltimore, Williams & Wilkins, 1991, 213 pp., \$29.00 (paper).

Last week, as my wife and I watched in awe a skilled librarian transform the congeries of 4,000 books into Dewey-decimal-ordered user-friendly rows, I could not help remembering Evaristo Zambo. When I was 12, I worshiped this Filipino conchologist, who discovered one of the world's rarest and most treasured seashells, the *Gloria maris*. When I asked him how he was able to single out that one shell when so many of us had recently combed the same beach and passed it over, he told me the origin of the word “serendipity.” He said that the secret of the success of the three princes of Serendip was in two key words: discernment and cataloging. Reading this amazing little book gave me this very same imagery. The fellowship of child psychiatrists is a small and cozy one because there are so very few of us, so I approached this book with suspicion when I read the foreword by Melvin Lewis, former editor of the *Journal of the American Academy of Child and Adolescent Psychiatry*. How could a book this small possibly live up to his almost idolatrous advanced billing? (“One might go so far as to say that no clinician should prescribe psychotropic medication for children and adolescents without having read such a book. Indeed, I can think of no other book that meets the needs of clinicians as does this one.”)

Dr. Green's work really is that good.

An associate professor of clinical psychiatry at the New York University School of Medicine and, along with his colleague Magda Campbell, recognized as an authority on child and adolescent psychopharmacology, Dr. Green gives the reader a sense of ease and familiarity as an avuncular tour guide of this infant discipline. He starts off immediately inside the front cover with a catalogue of 15 diagnoses in childhood and adolescence for which pharmacotherapy may be therapeutically indicated.

The sections entitled General Principles of Psychopharmacology With Children and Adolescents and Specific Drug Treatments should be required reading not only for all psychiatrists but also for all nurses and physicians who come in contact with any psychotropic medications. In my practice, I have come to realize that for the majority of my patients the family physician has already tried at least one psychotropic medication. The task of unraveling and teasing out the iatrogenic from the virginal disease picture becomes almost Her-

culean if not Sisyphean. Like the seasoned clinician, meticulous researcher, and skillful teacher that he is, however, Dr. Green takes us through maturational/developmental issues, relationship to the patient's family or caretakers, the process of explaining medication to the child or adolescent, medico-legal issues, baseline assessments, medicating the patient, untoward side effects, monitoring serum levels, length of time to continue medication, placebos, evaluating research studies, and specific drug treatments.

It is refreshing to hear Dr. Green expose false or dubious research. Child psychiatrists are often called on to treat patients under the age of 12 with medications that can be life-saving but are not officially recommended for these age groups because of inadequate research on children. Dr. Green says, "In evaluating the literature on child and adolescent psychopharmacology, it is important to remember that the fact that a drug is statistically significantly better than another drug or placebo does not necessarily mean that the drug is an optimal treatment for a given condition or for a specific child or adolescent. The drug may be effective only in certain environments (e.g., a laboratory) and not generalize to more ordinary circumstances, or it may improve only certain symptoms but not affect other major target symptoms to a clinically meaningful degree, or the overall improvement may be relatively modest with significant symptoms or deficits remaining."

Textbooks like this often suffer from an inescapable comparison to the television program that summarizes one day's National Football League game highlights in 3 minutes or less, something like watching a videotape of eight football games at fast forward. Such compendiums are usually encyclopedic, wobbly on supporting data, and cavalier or pompous. These criticisms do not apply here.

One of Franklin Roosevelt's favorite fantasies was spending an evening with an author and picking his brains. The reader of this book will get the sense that Dr. Green just happens to be in the neighborhood and is gladly spending that evening in an unharried, kindly, leisurely discussion of a topic he not only is inexhaustibly expert on but also hopelessly in love with.

TRUCE T. ORDOÑA, M.D.
Davenport, Iowa

Neuroleptic Malignant Syndrome: A Clinical Approach, by Gerard Addonizio, M.D., and Virginia Susman, M.D. St. Louis, Mosby Year Book, 1990, 167 pp., \$35.00.

In this excellent, clinician-oriented book, the authors industriously attempt to present the controversies in the literature on neuroleptic malignant syndrome and make recommendations based on a comprehensive and critical review of all the data. The book is organized into 13 chapters, beginning with a historical perspective followed by chapters dedicated to important aspects of this potentially lethal iatrogenic illness.

The literature on neuroleptic malignant syndrome consists mostly of case reports and is replete with divergent views on almost every aspect of this illness. This includes diagnostic criteria, demographics and risk factors, pathophysiology, and treatment recommendations. Most conclusions regarding the syndrome are drawn from a series of published case reports rather than from controlled, prospective studies. The authors present the controversies in the literature in an elegant fashion, including, for example, the diagnostic criteria of Levenson versus those of Keck et al., the role of lithium in causation of the

illness, and the issue of neuroleptic malignant syndrome being a spectrum illness.

Chapter 2 is excellently written and discusses the risk factors in neuroleptic malignant syndrome, dispelling myths regarding sex and age in relation to the illness. In addition, the authors provide important information on electrolyte disturbance and organic brain syndromes as predisposing factors to this illness. I would also like to highlight the chapter on differential diagnosis, which provides a clear and succinct discussion of events that should be differentiated from this illness, such as heat stroke, malignant hypothermia, and lethal catatonias. The discussion of pathophysiology is excellent, presenting the hypodopaminergic function theory of neuroleptic malignant syndrome, muscle contraction studies, hyperadrenergic states, and the role of γ -aminobutyric acid in causation of this illness.

Some important issues related to treatment are well presented in this book, such as the initial time interval before restarting neuroleptics, type of neuroleptic to be used, and the concept of prophylaxis with bromocriptine before starting neuroleptics. The issue of prophylaxis with bromocriptine is something new I learned from this book. The authors talk about the neuroleptic malignant syndrome occurring in non-psychiatric patients, in patients receiving nonpsychiatric medications such as metoclopramide, and in patients experiencing withdrawal from antiparkinsonian agents such as levodopa.

This book is easy to read, is a source of quick reference, and has excellent summaries at the end of each chapter in addition to tables listing all case reports and studies relevant to the topic of discussion. Technically the book is of high quality with good editing; typographical errors and misspellings are rare. The bibliography gives an extensive list of references pertaining to each topic. This book will not only prove useful for psychiatrists and trainees but also serve as a source of quick reference for family physicians, physicians in emergency rooms, and physicians in intensive care units. Reading this book is strongly recommended.

BRAIN AND BEHAVIOR

Psychopathology and the Brain, edited by Bernard J. Carroll and James E. Barrett. New York, Raven Press, 1991, 312 pp., \$131.50.

This volume was derived from proceedings of the 1989 meeting of the American Psychopathological Association, a meeting at which Walle J.H. Nauta was honored. Appropriately, the focus of the presentations concerned the brain, particularly new developments in neuroscience that provide better understanding of the brain systems involved in abnormal behavior. Five major topics—frontal/limbic/striatal mechanisms in psychosis, basal ganglia, behavioral biology and development, personality, and affective disorders—were discussed. The volume makes no attempt to cover all aspects of brain and behavior, purposefully omitting such significant areas as genetics, endocrinology, and pharmacology. Eight of the 14 chapters present data from human studies relating abnormal behavior to brain abnormality. The remaining six chapters present animal research germane to human behavior and development. Each chapter is followed by an abstracted discussion in which individuals attending the meeting com-

mented on the papers and presented questions or ideas from their own backgrounds. Many of these discussions are both lucid and helpful.

The volume covers a broad expanse of psychopathology and is dependent on one or two well-formulated presentations for each individual behavioral problem. Although not as complete as a textbook and not as current as a journal, the volume does provide an excellent overview of many of the important approaches being taken in the brain/behavior field through well-written and authoritative papers. For the individual physician or scientist interested in brain/behavior relationships but who has neither the time nor the energy to cull such information from the contemporary literature, this volume provides a superb and relatively up-to-date presentation.

D. FRANK BENSON, M.D.
Los Angeles, Calif.

The Psychoses of Epilepsy, by Michael R. Trimble. New York, Raven Press, 1991, 210 pp., \$68.50.

The development of psychotic symptoms in epileptic patients has been reported since the earliest days of medical writing. Recently the relationship between epilepsy and psychosis has generated considerable controversy. This volume, authored by one of the world's leading authorities on the coexistence of psychosis and epilepsy, appears destined to become a definitive reference for any psychiatrist who might become involved in caring for those afflicted with both an epileptic and a psychotic disorder.

In 11 clearly written, easily read chapters the author exposes the reader to current knowledge as well as controversial issues. The book presents all the pertinent data necessary to make a clear case that epilepsy certainly can have an impact on its victims' cognitive and emotional lives.

The first chapter sails through the history of the relationship between epilepsy and psychosis from antiquity to the twentieth century. This chapter is meant for those clinicians and researchers who are interested in epilepsy and psychosis. It provides a historical framework of the evolution of the thinking of laymen, scientists, and clinicians as they accumulated factual knowledge over the years.

The second chapter discusses the usual classification of the epilepsies (available in any neurology book), as well as a classification of the possible anatomical sites of the abnormal activity that directly bear on the behavioral manifestations of the different types of seizures.

The third chapter is written for nonpsychiatrists to familiarize them with the current classification of psychiatric disorders. Chapter 4 provides an anatomical overview of the limbic system and related brain areas and is required reading for those who plan to get involved in managing psychotic patients with epilepsy. It is no secret that most psychiatrists are not well versed in neuroanatomy. I would venture to say that studying this chapter is a minimum requirement for attempting to care for patients with both epilepsy and psychosis.

The fifth chapter, "Forced Normalization and Alternate Psychosis," is a good introduction to the complex relationship between these two brain disturbances. Forced normalization has been controversial, but this chapter provides a strong argument for its validity, supported by an exhaustive review of the literature.

Chapters 6-8 provide a full clinical description of the many psychiatric symptoms that have been associated with epilepsy. These chapters are indeed the meat of the book. Along with

chapter 10, which details the management of these patients, these three chapters should be read by any practitioner who might become involved in such patients' clinical care. A chapter on postoperative psychosis and another on the risk factors for the development of epileptic psychosis qualify this volume as a comprehensive text for its topic.

I feel that all psychiatrists need at least to look at selected chapters, but the whole volume is required reading for those who are involved in daily care of the psychoses of epilepsy.

NASHAAT N. BOUTROS, M.D.
Columbus, Ohio

ETIOLOGY AND NOSOLOGY

Schizophrenia Genesis: The Origins of Madness, by Irving I. Gottesman. New York, W.H. Freeman and Co., 1991, 284 pp., \$24.95; \$14.95 (paper).

Any clinician who has struggled to answer questions from patients' families such as, "Why did my son get schizophrenia?" or, "My wife's sister has schizophrenia, what chance does my daughter have of becoming ill?" will find the current work by Irving Gottesman a boon. However, *Schizophrenia Genesis: The Origins of Madness* is more than just a listing of risk tables. Cogent and engagingly written, the book not only presents the results of many studies from diverse fields but also elucidates the methods and the thinking processes that allow intelligent interpretation of their results.

The book begins with a brief review of the history of schizophrenia, including changing fashions in the concept of the disease. This leads to a discussion of the modern criteria for schizophrenia phenomenology. Dr. Gottesman then proceeds to introduce the fundamental concepts of psychiatric epidemiology. His central point is the concept of age-corrected morbid risk. He not only clearly describes this concept but explains its importance as a benchmark for comparing risk factors for schizophrenia among different studies. He then explains the basics of Mendelian inheritance.

With this groundwork, the reader is readily led through a discussion of classic family, twin, and adoption studies to the conclusion that there is indeed a familial (genetic) contribution to liability to schizophrenia but that environment influences the manifestation of this liability (the diathesis/stressor model). The next chapter describes patterns of mortality, cancer, suicide, criminality and violence, and fertility in schizophrenic patients, which leads to a discussion of public health policies and genetic counseling. Although he has previously provided rough estimates of the risk for different degrees of kinship, Dr. Gottesman emphasizes that an individualized approach to counseling is necessary for any putatively multifactorial trait such as schizophrenia. He describes computer-based risk assessment, the details of which are probably best left to professional genetic counselors. In the final chapter, Dr. Gottesman briefly touches on neurobiology to provide a "flavor" of the current efforts to understand the connection between genetic and environmental influences on the one hand and brain function on the other. He concludes with a description of molecular genetics and potential contributions from these techniques.

Some readers may object to the short shrift given neurobiology. However, the book provides a clear view of both the data and the underlying thinking that led an eminent re-

searcher in psychiatric genetics to a polygenic diathesis/stress-or theory of schizophrenia.

In addition to the wealth of data presented, the book also includes first-person accounts by patients and their families, presumably to enrich the reading experience beyond that provided by a sole discussion of clinical research results. Dr. Gottesman states that his intended audience includes the curious lay person as well as the mental health professional. In the absence of some basic background in science and mathematics, the book may be rough going. However, to any interested mental health professional, *Schizophrenia Genesis* not only provides valuable information but is enjoyable in the process.

STEVEN D. FORMAN, M.D., PH.D.
DANIEL P. VAN KAMMEN, M.D., PH.D.
Pittsburgh, Pa.

Etiology of Mental Disorder, edited by Einar Kringlen, Nils Johan Løvik, and Sverre Torgersen. Oslo, Department of Psychiatry, Vindern, University of Oslo, 1990, 211 pp., \$25.00 (paper).

This is an interesting book, in some ways quite useful and in many ways disappointing. It is a compilation of papers from an August 1990 World Psychiatric Association symposium in Oslo devoted to the topic of the title. Plenary sessions were held in the areas of schizophrenia, mood and personality disorders, child psychiatry, and senile dementia. The book itself is a compilation of several of the main papers from this meeting. Additional papers included in the volume are "Neurodevelopment and Schizophrenia" by Pilowski, Kerwin, and Murray, "A Summary of Psychiatric and Psychological Findings From the Minnesota Study of Twins Raised Apart" by Segal, Eckert, Grove, Bouchard, and Heston, and "Towards a Phenomenology of the Torture Situation" by Doerr-Zegers, Hartmann, Lira, and Weinstein. The organization of the book is quite interesting in that the papers presented at the meetings are published along with a discussion of the papers. In some cases the discussion is as informative as the papers, and in a few of the discussions the references considerably extend the main papers themselves. As with many texts that emanate from meetings, the papers are quite uneven and the volume suffers from a lack of integration. The strengths, however, are in the quality of the contributions themselves and in the presentation of some material that is not usually found elsewhere.

The first section, Child Psychiatry, consists of two papers. The first, by Steinhausen, "Etiology of Child and Adolescent Mental Disorders," is a very broad overview of the topic. Cederblad's discussion of this paper is brief but quite interesting and presents a somewhat independent view.

The second section, Schizophrenia, consists of papers by Tienari, Parnas, and Kringlen and a discussion of all three by Ciompi. The three papers relate to adoption studies, twin research, and longitudinal high-risk research, and the discussion is quite excellent and presents a model for the development of this illness.

The third section, Mood Disorders, includes a paper by McGuffin, Katz, and Bebbington on genetic transmission of mood disorders and another by Craig on the social etiology of depression. Katschnig provides a discussion of both papers. Although this section is somewhat brief there is a lot of attention to detail and the references are quite current. The exposition of genetic and environmental interactions is well done.

The fourth section, Personality Disorders, consists of a paper on the etiology of personality disorders by Torgersen and

a rather brief discussion by Reich. Torgersen's paper is a good overview of the problem with a pertinent reference list.

The fifth section, Senile Dementia, also contains one chapter, "Etiological Factors in Dementia" by Gottfries, and a discussion by Levy. Both the paper and the discussion are comprehensive.

Of the special papers included, the study on Minnesota twins raised apart was a good summary of this work.

Etiology of Mental Disorder is a paperbound book that actually took a fair amount of time to read. There are several tables and charts to illustrate overview concepts and data, and the chapters are somewhat longer than one usually expects from a symposium of this type. There are several typographical errors throughout the text. The overview by Kringlen at the beginning of the book reviews the content of each particular chapter and is quite useful.

DAVID L. DUNNER, M.D.
Seattle, Wash.

Problems in Differential Diagnosis: From DSM-III to DSM-III-R in Clinical Practice, by Andrew E. Skodol, M.D. Washington, D.C., American Psychiatric Press, 1989, 518 pp., \$44.00.

Psychiatric nosology is an amalgam of science, tradition, and convenience. In referring to a manual of diagnoses such as *DSM-III* or *DSM-III-R* it is difficult to know whether the source of a particular criterion is based in science, tradition, or convenience. This book is a tool to help us in that regard. The stated goals are to guide clinicians in the application of principles of differential diagnosis, place *DSM-III* and *DSM-III-R* in a clinical context, and bring together clinical and research traditions. It also serves the more important purpose of helping clinicians adapt to empirical psychiatry and has many features in its favor. All of the chapters are written by one author, which is a rarity these days. Actual case vignettes are used to discuss the *DSM* criteria, making the reading easier, but the book remains difficult to read.

There are 12 chapters, 10 devoted to syndromes and two to diagnostic interviewing and multiaxial diagnosis. The latter are the best written and contain many pearls of clinical wisdom; for example, on interview technique: "The interviewer is not considered successful if a diagnosis can be made but the patient becomes less willing to continue or seek treatment" (p. 2). It is gratifying to read that Dr. Skodol recommends a complete course in modern psychopathology as part of the training requirements for first-postgraduate-year trainees.

Several provocative statements are made, but the reader will be disappointed to find no discussion of these. To cite a few examples, regarding multiaxial diagnosis Dr. Skodol states that an axis is nothing more than a "clinical perspective" (p. 40), implying that a longitudinal/developmental perspective of hallucinations or dysphoria would make them axis II dysfunctions. In the chapter on psychosis he says without citing any literature that "hallucinations are indicative of psychosis only when the person experiencing them has no insight into their pathological nature" (p. 163). The implications of these concepts for pathophysiology and treatment are not mentioned.

The quality and depth of the discussions are variable. The problems remaining in *DSM-III-R* are fairly presented; in particular, Dr. Skodol points out where he differs from the official *DSM-III* and *DSM-III-R* versions, although he was very much a part of their development. The discussion pertaining to axes

III, IV, and V is limited. The use of axis III by nonphysicians is dealt with in one paragraph and stated to be a simple matter of recording the diagnoses made by a physician (p. 53). It is clear, however, as the author notes in his discussion of somatoform disorder (p. 336), that nonphysician clinicians are often asked to make judgments about physical disorders. As much as the criteria can be spelled out, their correct application is an issue of clinical judgment, and there is no substitute for medical training and experience in this regard. This is not brought out at all. The new convention introduced in *DSM-III-R* of rating severity is appropriately highlighted—for many years we have diagnosed patients without referring to severity—but there is no discussion of its overlap with axes IV and V or the utility of these axes. The 10 chapters on psychiatric syndromes do not have a common format, although most provide an introduction, a discussion of terminology, and an overview of the diagnostic and conceptual aspects of the syndromes. The changes from *DSM-III* to *DSM-III-R* are then critically reviewed, and a brief summary recapitulates the material.

In the chapter on organic mental syndromes, *DSM-III-R* innovations are well summarized, including the removal of the psychotic/nonpsychotic and acute/chronic dichotomies and the recognition that partial cognitive impairment is sufficient for a diagnosis of organic mental syndrome rather than the global reduction required in earlier *DSMs*. The point that organic personality syndrome is almost always from an illness intrinsic to the brain whereas organic mental syndromes could occur as a result of systemic illness elsewhere in the body is of practical utility. The table on pages 112–115 of systemic and CNS diseases that can potentially cause organic mental disorders is worth carrying in our pockets during rounds. The chapter on psychosis, on the other hand, does not fare well at all. Throughout the book, with the exception of the chapter on exotic syndromes, one is struck by the relative neglect of the international literature, and this weakness is most evident in this chapter. In the discussion of bizarre delusions no reference is made to the Jasperian criteria of understandability, historically the earliest one. In the discussion of negative symptoms, there are no references to the European work on their definition. In the discussion of schizophreniform disorder, there is no reference to Langfeldt's work (1) or the history and controversy behind the use of the term "schizophreniform" in *DSM-III*. In the presentation of the arguments to rule out an organic cause for schizophrenia there is no reference to the classic review by Davison and Bagley (2). Although it is noted that the diagnosis of acute psychotic episode is commonly used but has never had a place in the official nomenclature (p. 196), Dr. Skodol does not discuss the pros and cons of including such a diagnosis in *DSM*. Similarly, the advantages or disadvantages of deleting acute and chronic subtypes of delusional disorders in *DSM-III-R* are not discussed.

The changes made in *DSM-III-R* in the mood disorders are covered well, with particular attention to subtypes and terminology. Several aspects of the diagnosis of major depression that were confusing in *DSM-III* and that *DSM-III-R* overcame are lucidly presented. These include 1) setting the threshold for clinical significance, 2) the relationship of major depression to other diagnostic concepts of depression, 3) clinical utility of subtypes of depression, and 4) differential diagnosis from other mood disorders and normal grief. In the discussion of anxiety syndromes, Dr. Skodol notes the refinement of criteria for panic disorder, including the requirement of a crescendo pattern. Many subtle and useful distinctions between *DSM-III* and *DSM-III-R* regarding panic and phobic anxiety (pp. 285–286) are highlighted. The discussion of the relation

between panic and depression is good, and the discussion of psychological factors affecting physical illness is excellent (pp. 326–328). In the same chapter there is a simple and clear description of sexual dysfunction disorders.

A critical contribution of this book comes from the chapter on personality disorders. Dr. Skodol comments that the widespread practice of diagnosing a personality disorder after interviewing only the patient (with or without a structured instrument) is basically flawed and that diagnosing personality disorder in the presence of axis I disorders might not be valid. Yet these practices prevail widely. Dr. Skodol points out that it is critical to involve a third-party informant in the evaluation of personality. The main weakness of this chapter is that the discussion of an axis that would deal with defenses is limited, although the topic has aroused much controversy and continues to be heatedly discussed by nosologists.

Dr. Skodol notes that *DSM-III-R* was motivated by the experiences of clinicians in an explosion of research on nosologic issues in psychiatry, which is a surprising statement given that there were only 6 years between the two systems. The book is a good addition to the *DSM* library and very useful to nosologists. With *DSM-IV* on the horizon, however, clinicians might as well wait for the next edition to get the best value for their money.

SLEEP MEDICINE

Atlas of Sleep Medicine, edited by John W. Shepard, Jr., M.D. Mount Kisco, N.Y., Futura Publishing Co., 1991, 279 pp., \$150.00.

The *Atlas of Sleep Medicine* will serve as a landmark in the standardization of the field. The book provides a variety of photographs of actual polysomnographic recordings from patients with sleep disorders, captioned by several-paragraph explanations of the key features to be recognized in the recordings. Polysomnography serves the sleep disorders clinician in the analysis of sleep complaints in the same manner as the electrocardiogram serves the cardiologist in the analysis of chest pain. Until the publication of this atlas, there has been no standard reference to connect sleep disorders clinicians in different centers in their interpretations of the polysomnographic record.

The atlas is divided into ten sections. Section one, Recording Montage, outlines the individual recordings in a standard polysomnographic report. Section two, Recording Artifacts, outlines signals in the record that are extraneous to the variables of interest. Section three, Normal Sleep, shows recordings of different stages of sleep in adults, neonates, and children. Section four, Snoring and Sleep Disordered Breathing, shows recordings of snoring, hypopnea, cardiac arrhythmias associated with sleep-related breathing events, and central, obstructive, and mixed apnea as well as nasal continuous-

positive-airway-pressure correction of sleep apnea. Section five, Trend Oximetry, displays oximetry profiles showing patterns of oxyhemoglobin desaturations associated with sleep apnea. Section six, Movement Disorders and Parasomnias, shows examples of periodic limb movements, bruxism, REM-sleep behavior disorder, sleepwalking, night terrors, body rocking, and sleep-related panic attacks. Section seven, Epileptiform Abnormalities, shows polysomnographic recordings of epileptic activity during sleep. Section eight, Miscellaneous Polysomnographic Findings and Nocturnal Penile Tumescence, shows examples of such phenomena as hiccups and swallowing as well as examples of nocturnal penile tumescence recordings. Section nine, Daytime Sleepiness: Multiple Sleep Latency Test and Pupillography, shows examples of these recordings used in complaints of hypersomnia. Section ten, Actigraphy, shows recordings of wrist actigraphs used in a variety of clinical indications, such as sleep/wake schedule disorders, to give measures of daily motor activity over longer periods of time (for example, 1 week).

This clinical reference book is the combined effort of a highly competent staff at the Sleep Disorders Center of the Mayo Clinic and Mayo Foundation, Rochester, Minn., including John Shepard, Peter Hauri, and Cameron Harris. In all, 127 high-quality photographic reproductions of actual sleep recordings are displayed. With each is a rich, thoughtful guide to the individual case study, including interpretation of the record and recommendations for clinical management. The wise descriptions of the polysomnographic vignettes draw on the vast experience of the laboratory at the Mayo Sleep Disorders Center. Due to the specificity and technical nature of the atlas, it will be most beneficial to the sleep disorders clinician, although the clinical vignettes provide valuable insights for generalists attempting to understand the sleep complaints of their patients.

ERIC A. NOFZINGER, M.D.
Pittsburgh, Pa.

TREATMENT

Psychiatric Treatment: Advances in Outcome Research, edited by Steven M. Mirin, M.D., John T. Gossett, Ph.D., and Mollie C. Grob, M.S.W. Washington, D.C., American Psychiatric Press, 1991, 320 pp., \$25.00.

In 1624, John Donne wrote, "I observe the physician with the same diligence as hee the disease," and our paymasters have adopted this as their current motto. As a profession we physicians can no longer get by with the "because I say so" approach to medical practice. We are highly accountable these days, and our assessments of disease have to be objective, our treatments rational, and our results predictable.

This leaves psychiatry in a very difficult position because our syndrome descriptions and disease classifications are still quite unscientific. When we look at outcome results, not only are we uncertain of what has happened but in fact we are often not sure what it is we just treated. This is a reprehensible situation, particularly when, paradoxically, we continue to accumulate some potent therapies in several modalities.

Many of psychiatry's illnesses have very prolonged courses, and not many psychiatrists have the luxury of pursuing them from beginning to end, as Kraepelin and his contemporaries did. We have very few firm outcome criteria, and, worst of all, so far as statisticians are concerned, psychiatric illnesses do

not have much of a death rate, so it is difficult to give dramatic proof that our interventions save lives. That we are more in the business of saving quality of lives is not a terribly popular point of view to put forward to third-party payers these days.

It is bordering on the trite to say that the huge number of psychiatrically ill individuals in the community causes untold suffering and enormous economic loss. It is equally trite for psychiatry to say that it can do something about this unless we can prove that this is true and, equally importantly, show that our methods are better than anyone else's.

Psychiatric Treatment: Advances in Outcome Research makes a worthy, if somewhat tentative, attempt to break into the totally unsatisfactory situation we have today in outcome research in psychiatry, in which follow-up studies are sparse; measures of diagnosis, treatment, and outcome are idiosyncratic; and confirmatory investigations are rarely done. The editors state up front that the initiative to take a new look at outcome research in psychiatry in the United States is mainly a fiscal one. The managed care industry is making its demands, and psychiatry cannot plead special case status. Therefore, and this is the book's message, we had better learn how to define illness more clearly, treat it more specifically, and measure the outcome of the treatment more meaningfully. Otherwise, the management of our patients may be taken largely out of our hands.

The book is a series of edited essays discussing a fairly wide range of psychiatric disorders and emphasizing treatment outcome. Unfortunately, this field in psychiatry is pathetically meager, and one gets the impression that both editors and writers are scrambling for material. Despite its worthwhile aims, the book too often becomes bogged down in the obvious, and its message, although true, becomes repetitive.

At the present stage of development in psychiatry, the beginning of our treatment is too often geared to a short-term end. We have to begin to look much farther ahead and become aware of the fuller implications of disease outcome, so that our therapeutic plans can be realistically geared to the best-quality treatment and the best possible outcome for the patient. No insurer is going to be impressed if the "cured" patient continues to require frequent readmissions to an institution, and we as clinicians should not be happy with that state of affairs either.

Here in Canada, with our comprehensive medical care system, we tend to be smug about the open-market approach to health care in the United States. However, our system is under as much financial pressure as yours and we are increasingly being held responsible for the efficacy of our treatments and for their longer-term outcome. Because of the particular pressures on the U.S. system, you are becoming leaders in this area of research and practice, but the present volume shows very clearly how amateurish all of us are at present in delineating and measuring outcome factors. It should shame us into taking urgent action.

I have only one quarrel with the book's approach. Throughout, its message is more efficiency and more economy. Nowhere did I find a clear statement that, in the United States as in other developed economies, mental health services have always been desperately underfunded. Many of us are afraid that, in conforming with the need to make the rest of medicine more cost effective, psychiatry will be cut to the bone and beyond. I hope that future advances in outcome research will demonstrate not only our inefficiencies but also the enormous gaps in the services we are allowed to provide.

ALISTAIR MUNRO, M.D.
Halifax, N.S., Canada

Treatment Strategies for Refractory Depression, edited by Steve P. Roose, M.D., and Alexander H. Glassman, M.D. Washington, D.C., American Psychiatric Press, 1990, 160 pp., \$28.00.

Clinicians who turn to the psychiatric literature for help with patients with refractory depression are faced with a complex and diverse assortment of treatment recommendations. Although there is no shortage of advice available, strategies based on well-designed studies using standardized patient selection criteria and rigorously controlled treatment interventions are rare. In fact, most of the literature on which currently touted treatment recommendations for refractory depression are based consists of anecdotal reports and uncontrolled studies involving heterogeneous patient populations. Most studies are also short-term in nature and lack long-term follow-up data. Unfortunately, it also is common practice for clinicians to literally "experiment" on patients with various combinations of psychotropics before the safety and efficacy of such regimens are established. This type of polypharmacy would be considered unacceptable if held to the standards of therapeutic practice for other medical specialties. With the recent introduction of several new psychotropics and the increasing practice of applying "nonpsychiatric" drugs (such as calcium channel blockers) to psychiatric disorders, a concise analytic summary examining the scientific literature on the treatment of refractory depression has been needed. In this regard, this text, superbly edited by Roose and Glassman, is a valuable contribution to the clinical literature.

The reasons for the lack of methodologically rigorous studies of refractory depression are noted in the introductory chapter by Roose. Simply stated, the primary methodologic problem involves recruiting sufficient numbers of diagnostically homogeneous patients for statistical analysis and then rigorously sequencing treatment interventions over time as well as controlling for numerous potential confounding variables (particularly on axis II). After these basic problems, which are intrinsic to most currently available studies of refractory depression, are acknowledged, the remainder of the text coalesces and critically evaluates the treatment literature through late 1988. Topics that are examined include the relationship

between tricyclic serum levels and treatment response, lithium and thyroid augmentation strategies, and use of monoamine oxidase inhibitors. Applications of anticonvulsant medications such as carbamazepine and valproate are also discussed, and most of the emphasis is on bipolar disorder. The germinal literature on calcium channel blocking agents is discussed, but the more recent controlled investigations in this area supersede any dealt with here. The chapter on ECT focuses predominantly on response rates of patients who are resistant to antidepressant medication. A more timely and perhaps more useful focus for the ECT chapter would have been on the relative efficacy of unilateral versus bilateral electrode placement and the significance of charge dosing on treatment response. Clinicians seeking timely advice on these latter issues will also need to consult the more recent literature on ECT. The chapter on chronic depression and the role of axis II disorders in the phenomenon of treatment resistance has a predominantly descriptive and epidemiologic orientation. The contribution of developmental factors—particularly emotional deprivation and psychological trauma—are not examined. The psychotherapeutic and psychosocial management of patients with refractory depression is also not addressed.

These limitations largely derive from the limited scope that is inherent in the framework of the text, which is part of the Concise Guide series of the American Psychiatric Press, compiled from symposia presentations at APA annual meetings. From the standpoint of psychopharmacologic management, however, the text represents an extremely valuable compilation and critical analysis of the literature—at least through 1988—that should be quite useful to clinicians involved in the treatment of patients with refractory mood disorders. From an academic standpoint, the text also raises the standard by which future investigations and claims of therapeutic efficacy for refractory depression will be held. This should help facilitate standardized approaches in the clinical care of this difficult patient population.

Visual Hallucinations After Combining Fluoxetine and Dextromethorphan

SIR: I would like to report the occurrence of visual hallucinations in a patient treated with fluoxetine when she used a cough syrup containing dextromethorphan. To my knowledge, such interaction has not yet been reported in the literature.

Ms. A, a 32-year-old obese patient with a 20-year history of dysthymia, presented with manifestations of major depression. She complained of sadness and guilt, anhedonia, initial insomnia, and early morning wakening. She also expressed feelings of helplessness and hopelessness. A brief treatment trial with doxepin was terminated because of drowsiness and her fear of gaining more weight. A regimen of fluoxetine, 20 mg/day, was started. On the 17th day of treatment, Ms. A had symptoms of a common cold including congestion, runny nose, and cough. She took two teaspoonfuls of a cough syrup containing dextromethorphan. She had no prior side effects with that drug. The next morning, she took two more teaspoonfuls of the cough syrup with her fluoxetine capsule. Two hours later, she experienced vivid hallucinations of bright colors and distortions of the shapes and dimensions of her surroundings. The hallucinations lasted 6–8 hours, then stopped. They were very similar to her past experience with LSD 12 years earlier. Fluoxetine was discontinued at Ms. A's request. She also refused any other antidepressants. I continued to see her in therapy for another year, with some improvement, and without recurrence of the hallucinations.

Fluoxetine is a specific serotonin (5-HT) reuptake inhibitor (1), and dextromethorphan is an NMDA receptor antagonist related in its site of action to phencyclidine and ketamine (2). However, dextromethorphan does not have any known psychomimetic effects (3). It is known that 5-HT₂ receptors mediate the hallucinogenic effects of LSD (4). Also, there is some suggestion of a functional interaction between glutaminergic and serotonergic pathways (5). An electronic literature search did not produce any reports of visual hallucinations caused by fluoxetine or dextromethorphan. The patient used each of the drugs alone without side effects. The hallucinations appeared only when both drugs were combined. This suggests a synergistic action of the drugs in this patient. "Flashbacks" or "post hallucinogen perception reaction" may be another explanation. However, the long duration of the hallucinations (6–8 hours) makes this conclusion unlikely.

Acute Exacerbation of Body Dysmorphic Disorder During Tryptophan Depletion

SIR: Recent literature has examined the relationship between body dysmorphic disorder and obsessive-compulsive disorder (1, 2). Serotonin reuptake inhibitors have been reported to be effective in treating both conditions (3). We report effects of acute tryptophan depletion in a patient with a history of major depression and obsessive-compulsive disorder who met *DSM-III-R* criteria for body dysmorphic disorder. The patient participated in an ongoing study of the effects of acute tryptophan depletion on mood and obsessive-compulsive symptoms in patients with obsessive-compulsive disorder treated with 5-HT reuptake inhibitors.

Ms. A was a 42-year-old woman with a past history of major depression responsive to treatment with monoamine oxidase inhibitors (MAOIs). Most prominent throughout her course however, and unresolved with MAOI treatment, were obsessive concerns about her face and appearance, which fulfilled criteria for body dysmorphic disorder. Picking and filing at perceived facial imperfections consumed hours at a time, leading to wounds and secondary infections. Five years prior to the study reported here she developed counting rituals and compulsions involving symmetry and exactness, which prompted the additional diagnosis of obsessive-compulsive disorder. Treatment with clomipramine, 200 mg/day, and buspirone, 60 mg/day, was associated with near elimination of picking and filing, leading to healing of her face and a normal appearance at the time of examination. The patient did continue to spend up to an hour a day examining her face and obsessing about its imperfections. Her other obsessive-compulsive symptoms resolved completely.

Compared with sham depletion under double-blind conditions, acute tryptophan depletion produced a dramatic exacerbation in her dysmorphophobia. She became afraid that people were looking at her face, turned away from the open door of the testing room, and made repeated trips to the bathroom to stare in the mirror. The patient also became extremely tearful, reporting, "I don't know why I am crying all the time. I don't have anything in particular to

feel sad about." Sham depletion produced only very mild nausea, without change in the patient's affective state or level of concern regarding her face.

Administration of a low tryptophan diet coupled with an amino acid drink devoid of tryptophan has proven a safe and reliable method for producing lowered plasma tryptophan levels (4). Delgado et al. (4) have demonstrated the reemergence of depressive symptoms in depressed patients treated with 5-HT reuptake inhibitors when plasma tryptophan levels are acutely lowered in this manner. This effect is presumably mediated through a reduction in brain 5-HT, as decreases in plasma tryptophan have been shown to reduce brain 5-HT in preclinical studies (5).

The exacerbation of both depression and body dysmorphic disorder associated with acute tryptophan depletion suggests that 5-HT reuptake inhibitors used in the treatment of these syndromes share a common mechanism of action that depends upon the ongoing availability of 5-HT. That Ms. A's obsessive-compulsive symptoms were not exacerbated by tryptophan depletion is consistent with other preliminary results of tryptophan depletion in patients with obsessive-compulsive disorder treated with 5-HT reuptake inhibitors (Barr et al., unpublished data).

Effect of Estrogens on Thyroid Function

SIR: Estrogens are thought to exert rather minor actions upon intrinsic thyroid function, yet the literature concerning the effects of estrogens on thyroid function has provided conflicting results (1, 2). Oral estrogens are known to increase synthesis of thyroid binding globulin with a consequent rise in T_4 and T_3 , yet plasma concentrations of free T_4 and T_3 remain unchanged. Frank hyperthyroidism has not been described in association with estrogen use, yet the following is a case in which some symptoms typical of hyperthyroidism resolved after discontinuation of oral estrogens, corresponding with normalization in thyroid function tests.

Ms. A, a 21-year-old woman, presented with a chief complaint of, "I just can't stop crying." She had an 8-month history of crying episodes that had increased in frequency and duration, making her unable to work or interact with those outside her family. Psychosocial stressors were minimal; she denied feelings of sadness and neurovegetative

symptoms. On presentation, her only physical finding was sinus tachycardia (120 bpm); her only medication was ethinylestradiol 0.05 mg/norethindrone 1 mg, which she had been taking regularly for 1 year on a 28-day cycle.

Laboratory results were normal except for the following thyroid function tests: thyroid-stimulating hormone (TSH)=1.4 μ U/ml (normal=0.5-4.5 μ U/ml); T_4 =17.4 μ g/dl (5.5-11.8 μ g/dl); T_3 uptake=31.2% (35.9%-43.5%); and free T_4 index (FTI)=5.4 (2.3-5.23). Estrogen was discontinued, and 2 weeks later, thyroid function tests were largely unchanged (T_4 was 14.8 μ g/dl). There was little improvement in symptoms. Four weeks after discontinuation, crying spells were reduced by 50% (1-3 per 2 days), pulse was 100 bpm, and thyroid function tests were as follows: TSH=1.9 μ U/ml, T_4 =13.1 μ g/dl, T_3 uptake=32.9%, and FTI=4.31. Finally, 2 months after discontinuation, Ms. A was free of crying spells, thyroid function tests were normal (TSH=1.3 μ U/ml, T_4 =11.8 μ g/dl, T_3 uptake=36.6%, and FTI=4.25), pulse was 82 bpm, and she was completely functional.

Mood changes associated with oral contraceptive use are well documented; 60% of oral contraceptive users report some degree of affective symptoms, and 10% will discontinue their use due to depression or irritability (3). Our patient had a marked elevation in T_4 on presentation, atypical for estrogen use, and symptoms resolved as thyroid function tests normalized in the absence of exogenous estrogen. This is the first reported case that entertains the possibility of estrogens affecting behavior through alterations in thyroid function. Estrogens have been demonstrated to alter levels of TSH in vivo (2). However, evidence that the thyroid function test results may have been incidental is provided by Cohen's study in which 18% of adult psychiatric inpatients had abnormal thyroid function, and about 50% of these patients had a spontaneous normalization of values in 2 weeks (4).

Although direct cause of symptoms is not unequivocal, this case serves to expand the data regarding endocrine-associated psychiatric symptoms and aids the clinician in treating patients with psychiatric complaints who are using oral contraceptives.

Bupropion-Induced Carbohydrate Craving and Weight Gain

SIR: This letter reports the case of a 44-year-old man with a 12-year history of chronic pain and accompanying major depression of relatively recent onset.

Mr. A was seen in an outpatient pain clinic and found to suffer from recurrent major depression of approximately 4-month duration. The patient, in addition to displaying

several typical features of depression, also exhibited several "atypical" symptoms, including excessive eating, particularly when under stress (baseline weight=195 lb), prominent anxiety, and rejection sensitivity.

Mr. A developed severe urinary hesitancy after titration of doxepin to 100 mg h.s. This resolved during a 10-day washout period, and the patient was then started on a regimen of desipramine. After titration to 50 mg b.i.d., the patient developed severe urinary retention necessitating discontinuation of desipramine and treatment with bethanechol. Mr. A remained seriously depressed, with an essentially unchanged Hamilton Rating Scale for Depression score of 24 and a Symptom Questionnaire Depression T score of 90 (1).

After a 2-week washout period, the patient was started on bupropion at a dose of 100 mg b.i.d. for 3 days, increasing to 100 mg t.i.d. No side effects were noted at 2 weeks, and the patient reported much improvement in mood, sleep, energy level, and even anxiety symptoms. Mr. A also reported decreased sensitivity to criticism from others. At week 4, he had a Hamilton depression scale score of 12 and a Symptom Questionnaire Depression T score of 60. However, the patient exhibited a 12-lb weight gain and reported carbohydrate craving, particularly at night. Mr. A was so pleased with his overall response that he felt he could tolerate this modest weight gain. At 8-week follow-up, however, the patient exhibited a 31-lb weight gain from baseline and was quite disturbed at his continued carbohydrate craving, describing himself as "living in front of the refrigerator at night." Although the patient had maintained the improvements already cited, at his insistence, he was tapered off of bupropion over a 10-day period and treated with cognitive behavior therapy only. At a 1-month follow-up, the patient reported a return to his baseline appetite and exhibited a weight which was 15 lb over his baseline. He continued to deny significant symptoms of depression with a Hamilton depression scale score of 8. At a 2-month follow-up, his weight was only 6 lb over baseline, and his Hamilton depression scale score was 6.

Although the 1992 edition of *Physicians' Desk Reference* reports weight gain in 9.4% of patients treated with bupropion, as compared to 34.5% of patients treated with tricyclics, several major references in clinical psychopharmacology suggest that significant weight gain with bupropion treatment is rare (2, 3). Further, there is no reference to carbohydrate craving with bupropion in any of the major literature sources. Whether the severe weight gain and carbohydrate craving during treatment with bupropion was due to our patient's subtype of depressive illness (Mr. A exhibited a combination of both typical and atypical symptoms) is a question that requires research on the differential pharmacological response across depression subtypes. Also, further research into the mechanism of action of bupropion may help explain our observations.

Possible Clozapine Exacerbation of Bulimia Nervosa

SIR: Clozapine is a new antipsychotic agent reported to induce significant weight gain (1, 2). We report a case of a patient with bulimia nervosa and schizoaffective disorder whose bulimia became acutely worse after switching from thiothixene to clozapine.

Ms. A was a 29-year-old woman with a long history of bulimia nervosa that was followed by the development of a schizophrenic illness characterized by paranoid delusions, auditory hallucinations, and major affective symptoms. She was treated initially with thiothixene with a good response. Her bulimia and psychosis eventually stabilized on thiothixene, 10 mg h.s., and fluoxetine, 80 mg every morning.

After several months on this regimen, during which time Ms. A attended college, was nonpsychotic, and generally abstinent from binge eating and purging, she developed the initial signs of tardive dyskinesia. She was then switched to clozapine (up to 350 mg/day), which worked well for her psychosis with fewer side effects. During initiation of clozapine therapy she experienced no major psychosocial stressors and was maintained on fluoxetine, 80 mg/day. Ms. A began binge eating and purging approximately 6 weeks after beginning clozapine treatment, with as many as four binge-purge episodes per day. Before this time she had been completely abstinent for several weeks. The relapse of this patient's eating disorder continued for several months, did not respond to supportive and cognitive-behavioral techniques, and eventually required hospitalization. The patient gained over 17 pounds; however, her tardive dyskinesia was almost completely resolved 8 months after discontinuing thiothixene.

Although we did not switch back to thiothixene and rechallenge with clozapine, it is our clinical impression that the acute and marked changes following clozapine initiation strongly suggest an association. A resubstitution of thiothixene might more clearly establish this association, but we did not consider this to be ethical or clinically indicated. Although clozapine certainly offers great advantages over typical antipsychotic medications, we feel that the use of clozapine in the treatment of psychotic patients with a history of bulimia nervosa must be approached with caution, as vomiting can be life threatening. The subsequent electrolyte disturbances following vomiting may further predispose patients to seizures induced by clozapine. Since clozapine blocks serotonergic transmission, it may be that the exacerbation of this patient's bulimia involved compromise of serotonin function despite treatment with fluoxetine (3, 4). The development of tolerance to fluoxetine may be a possibility, but has not been reported to occur with bulimia.

No Gender Effect on Age at Onset in Familial Schizophrenia?

SIR: In the last decade, gender differences in schizophrenia renewed interest in the understanding of the heterogeneity of the disease. One of the most consistently reported gender differences in schizophrenia is the earlier age at onset observed in men (from 18 to 25 years) compared to women (from 25 to 35 years) (1). Although, Loyd et al. (2) found no gender effect for developing schizophrenia among the psychotic relatives of schizophrenic patients, Pulver et al. (3) reported a higher risk of developing schizophrenia in relatives of early onset male subjects and no association between age at onset and risk for schizophrenia among the relatives of female subjects. However, a large body of literature shows that the early onset syndrome in males with negative symptomatology and chronic evolution is characterized by an absence or a very low frequency of familial psychosis.

While identifying multiply-affected families for the purpose of linkage analysis, we surprisingly found no gender effect for age at onset of schizophrenia. A sample of 104 schizophrenic patients (70 men and 34 women), meeting *DSM-III-R* criteria and belonging to families containing at least one affected first-degree relative (sibling and/or parent), was identified in two French metropolitan and rural settings. All probands and relatives were interviewed with the Schedule for Affective Disorders and Schizophrenia—Lifetime Version Modified for the Study of Anxiety Disorders (SADS-LA). Age at onset was defined as age at first hospitalization, since this date is highly correlated with the beginning of acute symptoms and represents an exact measurement (4).

No difference was found between the mean age at onset among schizophrenic men (mean=24.0 years, SD=6.5) and women (mean=24.9 years, SD=7.2). This striking absence of difference in age at onset remained present at all age periods: 73% of men versus 63% of women had an age at onset between 26 and 35 years; and 6% versus 10% had an age at onset of 36 years or older.

The reported absence of a relationship between age at onset and sex cannot be attributed to an eventual cultural effect, since no statistical difference emerged when comparing the age at onset of the two subsamples of metropolitan (mean=23 years, SD=4.4) and rural patients (mean=25.1 years, SD=7.7). One should also point out that the age of onset of schizophrenia is not necessarily synonymous with first hospitalization. Thus, women could nonetheless have a later age at onset, while those hospitalized early could belong to a subgroup not tolerated any longer at home.

Still, our results could suggest that among multiply-affected families, schizophrenic men have a somewhat later onset than that usually reported in the literature. This supports the hypothesis that early onset syndrome in males is characterized by an absence of familial psychosis. This absence of gender effect for age at onset in multiply-affected families with schizophrenia should nevertheless be replicated in other populations of familial schizophrenic patients.

Gender Differences in Comorbid Anxiety and Mood Disorders

SIR: We recently analyzed diagnoses based on the Structured Clinical Interview for DSM-III-R (SCID) for a large consecutive series of patients seen at our Center for Cognitive Therapy. We believe our findings are somewhat unexpected. In particular, we found that the ratio of women to men is approximately 1:1 for anxiety or mood disorders for which there was no secondary axis I diagnosis, but approximately 2:1 for a comorbid disorder in which an anxiety or mood disorder was either the first or second diagnosis. In our series of 1,051 patients, we found these rates of primary and secondary mood and anxiety disorders for men and women, respectively: 14.4% and 15.5% for mood disorders only; 7.0% and 9.1% for anxiety disorders only; 10.2% and 19.5% for primary mood disorder plus secondary anxiety disorder; and 9.3% and 14.9% for primary anxiety disorder plus secondary mood disorder ($\chi^2=13.69$, $df=3$, $p<0.01$).

Our findings for the pure mood category stand in contrast to the usual reports (1-4) of mood disorders predominating in women, whereas our findings for the mixed anxiety-mood category are consistent with these prior reports. To our knowledge, prior studies of gender differences in mood disorders have not taken into account whether or not there is a coexisting anxiety disorder.

Our analyses suggest that there is a strong gender component to the mixed anxiety-mood concept. This may be of interest to investigators working to define a *DSM-IV* disorder around this concept.

We are interested in knowing whether other investigators have noted this gender difference.

Panic Disorder in Benin, West Africa

SIR: Studies of panic disorder among black Africans are very rare. We wish to report 32 cases of panic disorder diagnosed according to *DSM-III-R* criteria after a nonstructured clinical interview. The cases were systematically collected among 351 Beninese patients, whom I personally examined and followed during a 14-month period.

Nor only does panic disorder appear not to be rare in this population (prevalence rate in our patient population=9.1%), it presents many similarities to Western descriptions (1, 2). Although women were not overrepresented in the panic disorder group (17 women versus 15 men), the total patient population included more men than women (205 versus 146). Panic disorder patients were young; mean age at onset was 28 years (SD=9). Half of them (53%) had at least one attack per day with a mean duration of 39 minutes (SD=30). There was a great similarity in clinical aspect: the mean number of symptoms among the 13 symptoms from the *DSM-III-R* list was 7.1 (SD=2.0), with no symptom having a frequency lower than 30%. The two most frequent symptoms were the same as reported in Western studies: palpitations or tachycardia (81%) and dizziness (78%). Cognitive symptoms were not usually volunteered, but rather presented in the guise of somatic complaints (e.g., "heat in the head," a classic African expression of psychic distress [3]). However, upon inquiry it appeared that the Beninese patients experienced the same cognitive symptoms as Western patients: fear of dying (69%), fear of going crazy or doing something uncontrolled (31%). Cultural interpretation was sometimes needed. For instance, fear of going crazy could be expressed in this way: "During the attack, I could see myself walking naked in the streets." In black Africa only chronically mentally ill people walk naked in the streets. In a few cases patients developed persecutive concern about bewitchment, as is common in depressive African patients.

Comorbidity occurred with the same disorders as in Western countries (1, 2): agoraphobia (44%) and generalized anxiety (41%). Both agoraphobia and generalized anxiety were associated in 28% of the patients with panic disorder. Phobic reaction was provoked by going out in the street or to public places for 10 of the 14 agoraphobic patients. Sixty-nine percent of the patients with panic disorder had associated depressive symptoms, reaching the level of major depression (using slightly modified *DSM-III-R* criteria [4]) for 47% of that group.

Our data confirm that there seems to be little evidence available to suggest that panic disorders are fundamentally different in black Africa, either in prevalence or in form.

Besançon, France

The Serotonin Syndrome

SIR: In addition to the description of the serotonin syndrome by Sternbach (1), we would like to report a very severe syndrome following the administration of the serotonergic tricyclic antidepressant clomipramine.

Mr. A, a 30-year-old man with no medical history, had been recently hospitalized for major depression. He was suffering from recurrent major depression according to *DSM-III-R* criteria. Two previous depressive episodes, in 1987 and 1989, had been treated with maprotiline (75 mg/day) for the first episode and amineptine (150 mg/day) for the second. Neither of these two antidepressants induced somatic or psychotic complications. Upon the most recent admission, clinical examination was normal. Blood cell count, ionogram, hepatic biological parameters, calcium, and EEG were all within normal limits. The patient had been treated with clomipramine only, given orally. After the first administration of clomipramine (75 mg), he suffered from tremor, diaphoresis, and nausea. Eight days later, Mr. A was still receiving clomipramine, 100 mg/day. Tremor and diaphoresis persisted, and shivering and occasional myoclonic jerks (two or three per hour) of the limbs appeared. One day later, Mr. A became hypomanic, euphoric, ludic, and insomniac. No delirium was observed. His temperature increased slightly from 36.9 to 37.3 °C. Myoclonus became generalized. The patient complained of incessant, diffuse myoclonic activity involving mainly the face, the upper limbs, and the abdominal and chest muscles. Myoclonic contractions of the diaphragm and of the accessory respiratory muscles interrupted normal breathing. The patient was pale, with periorbital cyanosis and abundant sweating. The EEG was highly abnormal without ground rhythms. The main activity was in the delta range and included slow waves, or spikes and waves, or poly spikes and waves. Some of these paroxysmic features were synchronous with myoclonus jerks of the thoracic or abdominal muscles. The contrast CT scan of the brain was normal. The patient's clomipramine level was 0.3 g/liter (therapeutic range 0.5-1.0 g/liter). Clomipramine was stopped and Mr. A was transferred to an intensive care unit. After the concomitant administration of clonazepam (1 mg) and piracetam (1 g), myoclonus disappeared within 1 hour. Mr. A's mother told us that she had suffered, 5 years earlier, from mild myoclonus of the upper limbs after the administration of maprotiline, 75 mg/day, plus clomipramine, 20 mg/day.

This case appears to be rather exceptional for two reasons: 1) the only two published cases (2) of serotonin syndrome induced by clomipramine were observed in patients previously treated with clogyline, an MAO-A inhibitor; and 2) the myo-

clonus was especially severe. Meanwhile, Mr. A fulfilled eight of the 10 diagnostic criteria of the serotonin syndrome (1). Sternbach stressed that no predictive factors of serotonin syndrome are known. We would suggest that the existence, in the family, of a previous antidepressant-induced myoclonus could be a risk factor.

Interpretation of Language in Diagnostic Criteria

SIR: According to our survey of 30 professionals, there is a pronounced disparity in interpretations of the language in the "Diagnostic Criteria for Major Depressive Episode" in the *DSM-III-R*. This is of particular concern because those criteria are necessary for a number of diagnoses.

The first sentence of the "Diagnostic Criteria for Major Depressive Episode" (*DSM-III-R*, p. 222) is our focus: "At least five of the following symptoms have been present during the same two-week period and represent a change from previous functioning." In our survey, about two-thirds of the respondents interpreted this to mean that each of five symptoms must represent a change from previous functioning, while about one-third assumed that only one symptom needed to change as long as there are a total of five symptoms present during a 2-week period. We address the linguistic interpretation of the "Diagnostic Criteria," as well as a further convolution in the application of those criteria.

The sentence in question is a compound sentence. "At least five of the following symptoms" is the subject of the second clause, "represent a change from previous functioning." It is clear that the correct linguistic interpretation indicates that each of five symptoms must represent a change from previous functioning. This means that if four symptoms were present, say for 3 years, and some event caused a fifth to emerge, there still would not be a major depressive episode. However, we presented such a scenario in our survey, and respondents who had previously said that "a total of five symptoms must represent a change" were split in their assessment of whether a major depressive episode existed. Similarly, the respondents who said that "at least one of the five must represent a change" were also inconsistent in their assessments. In fact, the *DSM-III-R* implies that only one symptom must change by virtue of its assertion that "people with Dysthymia frequently have a superimposed Major Depression." Given that assertion, closer examination reveals that the similarity in the criteria between the two diagnoses makes it entirely unlikely, if not impossible, that all five criteria must change. In other words, there is a contradiction between the language, or the criteria, for major depression and the assertion of the existence and frequency of double depression. Also note other ambiguities; for example the word "previous" insufficiently specifies time with respect to a criteria like "feelings of worthlessness." While the *DSM-III-R* does state that "boundaries of Dysthy-

mia and Major Depression are unclear," there is no need for unclear language in the description of the diagnostic criteria involved in so many diagnoses.

Panic Disorder and Suicidal Ideation

SIR: Aaron T. Beck, M.D., and colleagues (1) recently reported that outpatients in the Center for Cognitive Therapy with a current diagnosis of panic disorder seldom report suicide attempts on a lifetime basis. The authors concluded that data from the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) study demonstrating an association between panic disorder and suicide attempts (2) were "anomalous, warranting further exploration."

1. *Replication of Findings Not Cited by Dr. Beck and colleagues.* Noyes (3) has recently published a comprehensive review of the literature on anxiety, panic disorder, and suicide. Included in his review were 16 follow-up studies, including his own 7-year follow-up study of 81 patients with panic disorder, which found that five patients had made serious suicide attempts, and three had died by suicide over the 7 years. Based on this review, Noyes concluded that the "data indicate that the risk of suicide in panic disorder is substantial."

Lepine et al., (4) drawing from an anxiety clinic in France, have reported that 42% of 100 consecutive patients with panic had attempted suicide (lifetime). Allgulander and Lavori recently reported on 3,302 inpatients with ICD-8-R "pure" anxiety in Sweden and confirmed an association with suicide (3).

Dr. Beck and colleagues point to a report from the ECA (5) on suicidal behavior that did not report panic disorder as a risk factor. A subset of these same ECA investigators have subsequently reanalyzed the ECA data (6) and concluded that we (2) were correct in our conclusion that panic disorder is related to suicide attempts.

2. *Comorbidity.* Dr. Beck and colleagues report on 151 panic patients. Did none of these have secondary depression, which might lead to suicide attempts? Did none of the 485 "mood disorders" patients have prior (or secondary) panic disorder or panic attacks? Results from Fawcett et al. (7) would suggest that the latter should be at increased risk for suicidal behavior. How were "primary" versus "secondary" diagnoses established if current diagnoses were used? Since Dr. Beck and associates only presented current diagnoses, it is not possible to answer these questions.

3. *Who is Referred to the Center for Cognitive Therapy?* The lifetime rate of suicide attempts even in the "mood disorders" group was only 7% in the data presented by Dr. Beck and colleagues. This is a lower rate than would be expected in a clinical sample of depressed patients. Thus, patients coming to the Center for Cognitive Therapy may be a filtered group of psychiatric patients. It is possible that the filtering takes place in the referring source rather than among Dr. Beck's staff. With all due respect to Dr. Beck's fine research on hopelessness and on cognitive therapy, it is still quite possible that patients with a history of suicide attempts are less likely to be referred to a center for cognitive therapy, especially if they have comorbid diagnoses. For example, 49% of 954 depressed patients coming to treatment at six university cen-

ters as part of the NIMH Collaborative Study of the Psychobiology of Depression gave a history of suicide attempts.

Discrepancies in rates of attempts across clinical samples have more to say about differences in clinical protocol screening and local referral practices or "self-selection" into specific treatments than they do about the true rate of suicide attempts in persons with mood or panic disorders in the community.

We conclude that the findings are not anomalous and certainly warrant further exploration on their nature and cause.

MYRNA M. WEISSMAN, PH.D.
GERALD L. KLERMAN, M.D.
JIM JOHNSON, PH.D.
New York, N.Y.

SIR: Dr. Beck and associates reported on the lack of association between panic disorder and suicidal ideation and behavior in clinical populations, in contrast with previous research evidence mainly based on epidemiological studies (1). We investigated the occurrence of suicidal ideations and attempts in a consecutive series of 70 outpatients referred to our Affective Disorders Program (48 women and 22 men; mean age=34.2 years, SD=9.5 years), five of whom satisfied the *DSM-III-R* criteria for panic disorder with agoraphobia. Patients with concurrent major depressive disorder were excluded. Suicidal tendencies were evaluated by the 7-point scale of Paykel's Clinical Interview for Depression, a semistructured research interview (2). This scale consists of specific anchor points, from "no suicidal ideations" (score 1) through "patient has thoughts of taking his life, but would not, and has no plans" (score 4) to "suicidal attempt of any but most minor kind" (score 7). The cut-off point of 4 was found to apply to 75% of patients with *DSM-III* melancholia and to 5% of healthy control subjects (3). Only one of the 70 patients with panic disorder and agoraphobia (1.4%) reported suicidal tendencies, as identified, in the previous month. These findings thus support those by Dr. Beck and colleagues.

Dr. Beck and colleagues discuss several potential explanations for the discrepancies between their clinical study and epidemiological findings (1). We agree that undetected or previous history of mood disorders may be particularly important regarding suicidal behavior. We have data, however, to suggest another explanation of suicidal ideations. Fear of dying is a rather common symptom during panic attacks. In some cases, it may occur also at other times and reach the

intensity of thanatophobia, the unfounded conviction of dying associated with fear of news that provokes thoughts of death (4). Thanatophobia, as measured by Kellner's Illness Attitude Scales, was found to be significantly higher in patients with agoraphobia associated with panic attacks, compared to healthy control subjects, and to wane when agoraphobia was treated by behavioral methods (5). Thirty-eight patients (54.3%) of the 70 here reported scored 4 or above for thanatophobia on the phobia item of the Clinical Interview for Depression. It is rather common in various research interviews to start exploring suicidal ideations by asking whether there has been a period when the patient thought a lot about death. The majority of patients with panic disorder and agoraphobia were found to be obsessed by the idea of death, and yet these thoughts are part of hypochondriacal concerns (4). Unlike experienced clinicians, lay interviewers in epidemiological studies may be misled by these thoughts and interpret them as part of suicidal tendencies.

Dr. Beck and Colleagues Reply

SIR: Although our article was published in September 1991, we wrote it shortly after reading Dr. Weissman and associates' 1989 article (1). Therefore, we are indebted to them for describing more recent reviews and studies. We concur that the original findings can no longer be considered "anomalous." We address their points below.

1. *Replication.* A critical review of the literature is beyond the scope of this letter. However, many of the studies cited by Dr. Weissman and colleagues are not so supportive as suggested. For example, the 16 studies reviewed in the article by Noyes consist of eight retrospective studies of the relation of *neuroses* (not panic disorder) to suicide attempts and eight retrospective studies of the relation of *anxiety states* or *anxiety neuroses* to suicide attempts. Several of these samples included patients whose diagnoses antedated by several decades the inclusion of panic disorder as a separate entity in *DSM-III*. Also included in this review were six studies of completed suicides, none of which showed a relationship between panic disorder and suicide.

2. *Comorbidity and Multiple Diagnoses.* To test the issues about comorbidity raised by Dr. Weissman and associates, we identified a sample of 559 (31.2%) of 1,794 outpatients consecutively evaluated according to *DSM-III-R* criteria at the Cen-

ter for Cognitive Therapy between 1986 and August 1991 who represented the types of diagnostic combinations that Dr. Weissman and colleagues suggested might be evaluated with respect to past suicide attempts. We excluded patients from 1985 because some of them were diagnosed according to *DSM-III* criteria. All of the current patients were diagnosed with the SCID, and the information about a past suicide attempt was gathered with the Scale for Suicide Ideation as in our previous study. Instead of focusing on just secondary comorbid diagnoses, we extended our scope to tertiary diagnoses.

None of the 53 patients diagnosed with a primary panic disorder for whom there was no comorbidity described a past suicide attempt. Five (3.6%) of the 140 patients diagnosed with a primary panic disorder and either a secondary or tertiary mood disorder described a past suicide attempt. Twenty (6.4%) of the 310 patients diagnosed with a primary mood disorder for whom there was no comorbidity described having made a past suicide attempt, while four (7.1%) of the 56 patients diagnosed with a primary mood disorder and either a secondary or tertiary panic disorder described having made a past suicide attempt. In summary, the presence of a mood disorder, whether primary, secondary, or tertiary, was the consistent correlate of previous suicide attempts.

3. *Referrals to the Center for Cognitive Therapy.* Our finding of 7% for lifetime suicide attempts may not be low for an outpatient sample. In the study by Fawcett (cited by Dr. Weissman and colleagues), 80% of the sample consisted of inpatients, many of whom presumably had been hospitalized because of recent suicide attempts.

A major question is the ascertainment of suicide attempts. Many individuals report having made "suicide attempts" but acknowledge not having had any wish to die. It is possible that our stringent criteria for ascertainment of lifetime suicidal attempts may account for what appears to be a low rate. In any event, there is no discernible basis for the suggestion that patients referred to our clinic were screened out for previous suicide attempts. Regarding the "filtering hypothesis," we have determined that our entire sample of patients has a substantial degree of suicidality. In fact, 587 (32.7%) of 1,794 patients in all diagnostic categories presented with current suicidal ideation.

We recommend that further research, particularly prospective studies, should address a number of methodological, clinical, and conceptual issues before we can arrive at any definitive conclusions. Our recommendations include the following:

1. *Ascertainment of suicide attempts.* A more refined definition that restricts "suicide attempts" to instances in which there is an intent to die and classifies other acts as "deliberate self-harm" or "parasuicide" is suggested.
2. *Definition of panic disorder.* The policy of equating diagnoses of "anxiety states" with the diagnosis of "panic disorder" appears to be unjustified.
3. *Sequence.* Some kind of program needs to be laid out to address the questions of sequence and of proximal versus distal relationships of clinical diagnoses and suicidal attempt.
4. *Comorbidity.* Data should include all of the clinical conditions that can be associated with suicide attempts: affective disorders, multiple diagnoses, depression-anxiety combination, personality disorders (especially borderline personality disorder), and substance use disorders.
5. *Comprehensive study of hypotheses.* Convergent validity of the hypothesized association between panic and suicide should be established on the basis of a variety of related studies: a) community surveys (as in the studies by Dr. Weissman and colleagues), b) clinical examination

of recent suicide attempters, c) examination of individuals currently diagnosed as having panic disorder, d) "psychological autopsies" of completed suicides, and e) longitudinal prospective studies of panic disorder and affective disorder patients.

We appreciate seeing the letter from Dr. Fava and associates who point out several possible sources of error (fear of death, hypochondriacal fixations, etc.) in categorizing death-related thoughts as suicidal ideation. Their overall finding that suicidal ideation is not specifically associated with panic disorder raises further questions regarding the issue of panic disorder as a risk factor in suicidal behavior.

Seizure With Low Doses of Clozapine

SIR: I refer to a letter to the Editor by Pierre Thomas, M.D., and Michel Goudemand, M.D. (1). From the letter it appears that the patient in reference was prescribed clozapine after he did not respond to treatment with haloperidol, 20 mg/day. If this is so, by current standards prevalent in the United States, the use of clozapine would have been premature.

Use of a medication with the potential for complications that is carried by clozapine should be reserved for cases where alternative treatments have been reasonably exhausted. While most patients would respond to haloperidol, 20 mg/day, some patients may require higher doses, and if that failed, a trial with another "conventional" neuroleptic would have been in order. I hope that the letter of Drs. Thomas and Goudemand will serve to encourage us to maintain these standards.

REFERENCE

1. Thomas P, Goudemand M: Seizure with low dose of clozapine (letter). *Am J Psychiatry* 1992; 149:138-139

JOSEPH MORE, M.D.
Middletown, Conn.

Dr. Goudemand and Dr. Thomas Reply

SIR: We agree with Dr. More's advice about the reserves and precautions to be taken before implementation of clozapine treatment.

However, our purpose was to mention an unusual adverse effect (seizure with low doses of clozapine) and consequent particular precautions (i.e., during EEG) to be taken while increasing dosage. Thus, we did not go deeper into the reasons why our patient was prescribed clozapine treatment. With haloperidol treatment, psychotic features and delusions persisted unchanged, moreover, our patient experienced incapacitating and incorrigible extrapyramidal symptoms. In our clinical experience such a combination required an increase in dosage, as well as the use of another "conventional" neuroleptic.

In our ward, since 1989 only 10 patients have been pre-

scribed clozapine among about 150 patients admitted for schizophrenic disorders each year. We hope this ratio testifies to our respect of the "standard" in prescribing clozapine.

The choice of a treatment is made after careful consideration of a patient's individual situation and after weighing benefits and disadvantages. Exclusive and uniform "standards" may damage quality of clinical practice.

PIERRE THOMAS, M.D.
Lille, France

Psychiatric Consultation-Liaison Intervention and Hospital Stay

SIR: I read with much interest the article by James J. Strain, M.D., and colleagues (1) examining the effect of a psychiatric consultation-liaison intervention on length of hospital stay and disposition status of elderly patients with hip fractures. The authors concluded that admission psychiatric liaison screening of these elderly patients resulted in early detection of psychiatric morbidity, better psychiatric care, earlier hospital discharge, and substantial cost savings to the hospital. However, the design of their study raises questions as to the specificity of the effect of psychiatric screening on reducing length of stay and thus the cost savings generated.

The design of their study, comparing the outcomes mentioned above among patients in an orthopedic unit between a nonintervention (or "control") year and a subsequent psychiatric intervention year, has its limitations. Perhaps the greatest weakness of this design is that it is not possible to be sure that the reduction in length of stay observed during the intervention year was due to the specific effect of psychiatric screening rather than nonspecific factors such as the effect of observation on the orthopedic unit's practices. Unfortunately, it is not clear whether the authors incorporated an appropriate experimental condition during the nonintervention year that would control for such nonspecific effects of observation, thus weakening the evidence for their conclusions. Furthermore, demographic (age, gender, marital status, socioeconomic class) and clinical (premorbid level of function) variables that could affect length of stay may have differed between the control and intervention years. However, data were not presented showing comparability of intervention and control years with respect to these factors, again weakening the inferences that can be made about the impact of psychiatric intervention.

While designing a study to address these methodological issues may be difficult, if not impossible, one way of obtaining indirect evidence for the specific effect of psychiatric intervention in reducing length of stay would be the demonstration that the reduction in length of stay seen in the intervention year was confined to patients with, rather than without, psychiatric comorbidity. Further, it would be reassuring to know that patients with psychiatric comorbidity in the intervention year had a shorter length of stay than patients with equivalent comorbidity in the control year.

Despite these criticisms, I congratulate the authors on attempting an important study in such a methodologically complex area. Perhaps the limitations of their method might have warranted some discussion in their article.

H, Nordlie J, Sacks C: Cost offset from a psychiatric consultation-liaison intervention with elderly hip fracture patients. *Am J Psychiatry* 1991; 148:1044-1049

PHILIP MORRIS, M.D., PH.D.
Baltimore, Md.

SIR: We read with great interest the recent paper by Dr. Strain and colleagues. However, we question the authors' basis for their conclusions.

The early detection claim seems self-evident, but it is unclear if the *DSM-III-R* diagnoses presented were made just at admission or at any time during the hospitalization. It is not unusual to find delirium appearing several days after surgery (1). Delirium should be separated from dementia since the interventions and prognoses are quite different and the latter is often known prior to admission and does not require a psychiatric consultation to detect it "early" in the hospitalization. With respect to depression, were any of the patients prior to admission taking antidepressants that could cause orthostatic hypotension and lead to falls and fractures?

The claim of "better psychiatric care" is hard to evaluate without any data on what psychiatric care was provided. At Mount Sinai patients were only seen for 2.4 visits on average. Were medications added or stopped? Was psychotherapy provided to patients or families? Was the diagnosis used to improve discharge planning?

The claim of "earlier discharge" is impossible to evaluate since the data from the intervention year were compared to a baseline year without any evidence that the populations were identical or that nothing had changed in terms of pressures on length of stay.

The claim of "substantial cost savings" rests on unspecified assumptions as to how the hospitals are reimbursed or could reduce expenses. It is unclear what the full cost (direct and indirect) is of the psychiatrist's time for the liaison and consultation activities. Is the \$80/visit the charge or payment? For what kinds of visits? Why didn't "better psychiatric care" lead to any cost savings from more patients going home rather than to expensive nursing homes? Change scores at discharge for the Geriatric Depression Scale and the Mini-Mental State exam should be calculated for individual patients in relation to their own scores at admission and not in comparison to a different group of patients in the baseline year.

Some of the above analyses may be possible with the data available to the authors and should be presented. However, given the methodological problems with the study, it may still be impossible to evaluate the authors' conclusions.

BENJAMIN LIPTZIN, M.D.
DANIEL FRIEDENSON, M.D.
Springfield, Mass.

Dr. Strain and Colleagues Reply

SIR: We appreciate the comments of Dr. Morris and Drs. Liptzin and Friedenson. Dr. Morris has invited our attention to the issue of study design. First, the design was different at

the two study sites: Mount Sinai had a baseline nonintervention year compared to the intervention cohort (only one orthopedic unit), whereas Northwestern Memorial Hospital had a contemporaneous control (three orthopedic units) (table 2 in our article). Control and experimental observations were occurring during the same time period. Therefore, Dr. Morris's concern about nonspecific factors has been mitigated at the Northwestern site. Second, the demographic variables: age, sex, marital status, and seriousness of medical illness (Horn Severity of Disease Rating) were not significantly different between the baseline control and intervention years. Data analyses underway will answer Dr. Morris' third question as to whether or not the patients with treated psychiatric morbidity had a shorter length of stay in the experimental year. However, the nature of the liaison intervention could have impacted upon patients without frank psychiatric morbidity as well; e.g., problems of coping, disturbances of mood, families reluctant to take home an impaired elderly patient, changing long-acting hypnotics to short-acting forms, which permitted patients to attend morning physical therapy that may have otherwise been missed. Therefore, it would not have been expected that only patients with psychiatric and medical comorbidity would have shortened length of stay secondary to the liaison intervention.

Space limitations restrict addressing all the issues raised by Drs. Liptzin and Friedenson. Admission and discharge clinical assessments, i.e., clinician-evaluated *DSM-III-R* diagnoses and rating scales, were employed. The majority of the organic mental disorders were delirium (75%), and few were referred for psychiatric consultation. In contrast to the baseline year when psychiatric consultation was requested and provided to only 10% and 2% of the elderly hip fracture patients at Mount Sinai and Northwestern Memorial Hospital, respectively, the liaison screen during the intervention year resulted in psychiatric evaluation and treatment (if necessary) of 79% and 61% of the patients, respectively. Patient visits (average=2.4) in no way reflect the total system intervention of liaison psychiatry, which addressed the *denominator* (all the patients) rather than the *numerator* (only those referred). A *contemporaneous* control cohort at Northwestern was observed simultaneously with the intervention group that stayed 2 days less in two disparate hospitals.

Those outliers who were in excess of two standard deviations because of medical complications and/or new illnesses (e.g., myocardial infarctions, cerebral vascular accidents), were appropriately omitted from the sample.

All patients had Medicare or third-party insurance. The hospital was losing money on every patient who exceeded the diagnosis-related group (DRG) reimbursement of \$7,500, and costs and charges were two and three times this reimbursed rate. If the patient could be discharged sooner, the costs would more closely approximate the DRG reimbursement rate. Since orthopedic beds were at a premium at the two hospitals studied, decreased length of stay would permit more admissions and result in a decrease in the losses these patients were incurring for the hospital. The hospital does not need to reduce its variable costs by reducing staff, but rather by admitting more patients for a shorter length of stay. Psychiatrist-ordered tests were a rare event and had a negligible effect on the \$14,000 cost per patient.

The amount of psychiatric time for the study was 15–20 hours per week per hospital, funded by an NIMH grant. This could be covered by a fellow or junior attending psychiatrist employed half time at a cost of approximately \$25,000.

It is routine to report group means, which represent average change, to compare control and experimental results on stand-

ard measures of psychiatric status. The two groups were significantly different in the amount of time that passed between initial and discharge assessment. This difference required us to adjust the comparison between liaison and control conditions to compare the relative clinical efficiency. This adjustment cannot be accomplished on individual change scores due to the variation in length of stay within each group. Analysis of covariance, for instance, would be completely inappropriate in this case, due to the correlation between the length of stay and the independent variable (liaison versus control).

The department of orthopedics at the Mount Sinai Hospital is supporting the psychiatric screening of all elderly patients with traumatic injury on their service.

Competency to Make a Will

SIR: I would like to present two thoughts that might be helpful to psychiatrists who are asked to perform a forensic consultation to assess competency to make a will (1):

1. It has been my experience that, according to the American Association of Psychiatry and Law, Ethical Guidelines, "A treating psychiatrist should generally avoid agreeing to be an expert witness or to perform an evaluation of his patient for legal purposes" (2). The role ambiguity and conflict, as well as the loss of both the confidentiality essential to a therapeutic alliance and the objectivity essential for a forensic consultation, can be best avoided by splitting such dual roles with the individual patient between two clinicians: the treating psychiatrist and the forensic psychiatrist (3).

2. Even with the organically impaired patient, psychodynamically driven affective factors such as pathological grief can be major influences on competency. When the forensic psychiatrist encounters such a case, referral for appropriate treatment and a subsequent reevaluation of competency is warranted (4).

HAROLD J. BURSZTAJN, M.D.
Cambridge, Mass.

Dr. Spar and Dr. Garb Reply

SIR: We are grateful to Dr. Bursztajn for his valuable postscript to our article, in which space limitations precluded our addressing the relationship between the roles of consulting expert and

treating physician. Because of the likely breach of confidentiality entailed by expert testimony, as well as the need for expert objectivity, the treating physician is, as Dr. Bursztajn points out, generally a poor choice for this role. There are three exceptions: 1) if the expert contribution is limited to providing advice and consultation rather than testimony; 2) if the doctor-patient relationship has ended and the patient agrees to waive confidentiality; and 3) if litigation arises (as is frequently the case) after the patient's death. Although the question of objectivity remains in each of these cases, the greater weight afforded the opinions of an expert who has gained familiarity with the patient through a therapeutic relationship will frequently outweigh these concerns.

We also agree with Dr. Bursztajn that the expert may, at the discretion of the parties requesting the consultation, recommend various interventions, including psychiatric or general medical treatment. An interesting potential ethical dilemma for the expert is posed if the testator lacks testamentary capacity due to a treatable condition but the requesting parties are satisfied with the status quo and either do not ask for or reject recommendations for treatment!

Suicide Among Homosexual Youth

SIR: The otherwise excellent review on suicide by Herbert Hendin, M.D. (1), fails to address the increased vulnerability of homosexual youth for suicide.

Several recent reports show this problem to be serious. Remafedi and Farrow (2) reported 41 suicide attempts among a sample of 137 gay and bisexual youth. Rotheram-Borus (unpublished report) studied three groups of minority youth and found that 28% of all subjects, but 41% of gay and bisexual subjects had attempted suicide. The United States Department of Health and Human Services (3) has stated that gay and lesbian youth are two to three times more likely to attempt suicide than other youth.

The formation of sexual identity is always characterized by sexual and emotional changes, but homosexual youth must also contend with widespread negative social attitudes. As a result, family and peer condemnation rather than support is often evident. Hetrick and Martin (4) reported that one-third of 329 gay adolescents had been subjected to violence because of their sexual orientation; 49% of this violence was at the hands of family members. Twenty percent of their subjects had either attempted suicide or had prominent suicidal ideation. In addition, many gay youths experience anxiety about the risk of HIV infection.

Homosexual youths are often unable to find someone knowledgeable with whom they can comfortably discuss these problems, including individuals who have successfully integrated a gay or lesbian identity. This may lead to overwhelming isolation and depression.

Youth suicide is now an epidemic and the object of national concern. Suicidal behavior among gay and lesbian youth is an epidemic within an epidemic that remains largely unknown. It is hoped that future contributions to the psychiatric literature on suicide will recognize and address this problem.

Dr. Hendin Replies

SIR: I agree with Dr. Prenzlauer and his colleagues in believing that the subject of suicide and attempted suicide among homosexuals requires special attention.

In my own studies of college students who made serious suicide attempts, I found, as did the authors cited by Dr. Prenzlauer and associates, a disproportionate number of male and female homosexuals among the suicide attempters. Their suicide attempts were usually precipitated by an overt rejection or abandonment by someone with whom they were currently involved. In every case there was a history of early maternal abandonment which was not present among homosexual students seen in our control group who were not suicidal (1, 2). Guilt or shame over being homosexual was not a significant factor in their suicidal behavior.

There is, however, some evidence based on questionnaire responses from individuals in homosexual college organizations and "rap" groups that suicidal ideation and past suicide attempts were influenced by social rejection for being homosexual in young men conflicted about their homosexuality (3). Evidence based on controlled studies that included homosexuals seen immediately after a suicide attempt is needed before any linkage between such experiences and suicidal behavior could be established. Although all homosexual young people have to contend with the negative social attitudes that Dr. Prenzlauer and colleagues describe, there is so far no evidence that suicidal homosexuals who have killed themselves have suffered more from these attitudes than nonsuicidal homosexuals or that such attitudes are a major factor affecting the suicide rate of homosexuals (4).

Studies of actual suicide have, so far, not confirmed that there is a greater incidence of homosexuality than to be expected among the suicides. The comprehensive Robins study based on data gathered originally in the late 1950s found no homosexuals among the 134 subjects of whom 103 were male (4). Accepting a male homosexual rate of 5% in the population (most estimates are greater), the finding is statistically so improbable ($p=0.005$) as to suggest that the greater concealment of homosexuality in that time period influenced the result.

The more recent comprehensive study by Rich et al. (5) concluded that the rate of suicide among homosexuals is not greater than that for heterosexuals. Significantly, all of the homosexuals in the Rich sample, were males in the age range between 21 and 42 years. That no homosexuals were present among the 83 men older than 42 years among the sample who killed themselves is also so improbable as to suggest that concealment may still be a factor affecting the figures in the older group. The need for concealment is of course a reflection of

the negative social attitudes that Dr. Prenzlauer and colleagues address.

Multiple Personality Disorder: A Factual Error

SIR: J. Modestin, M.D. (1), quoted our work on multiple personality disorder in India (2) and attributed to us the hypothesis that the patients with the same "basic fault" in India are more prone to develop *hysterical psychosis* in comparison to multiple personality disorder in the United States.

We did speculate whether "possession syndrome" and multiple personality disorder represent the cross-cultural variants of the same dissociative disorder in India and the United States respectively, but we did not suggest the same about hysterical psychosis. Dr. Modestin seems to be unaware of the literature emanating from India on face and descriptive validity of possession syndrome (2-5) and naively substitutes it with "hysterical psychosis."

An informed awareness of the literature on both these entities would suggest that they are not the same. Possession syndrome certainly is a dissociative disorder seen in South Asia, but it is not a psychotic illness. We still reiterate our original hypothesis that the unavailability of the diagnostic category of "possession syndrome" and similar dissociative disorders in the current U.S. diagnostic system may be one of the reasons for overdiagnosis of multiple personality disorder in this country.

Dr. Modestin Replies

SIR: The possession syndrome is known in many cultures (1). Even though it may take on special transcultural forms (2) and in that case, perhaps, represent a special culture-bound entity, it has always been considered an expression of hysteria or schizophrenia in most cases by Western psychiatrists (1, 3, 4). The immediate basis of my "naive substitution" of possession syndrome with hysterical psychosis is, however, the paper by Adityanjee et al. In that paper they themselves talk about "spirit possession—perhaps a form of *hysterical dissociation state*" and about "the documented high prevalence of *hysterical possession* in India [emphasis added]." So if they consider the possession syndrome to be different from hysteria, which, incidentally, has by no means been generally proven, they should be more careful in their own formulations. The descriptive criteria for a psychotic disorder, as defined, e.g., by Research Diagnostic Criteria (5), will most probably be met in the vast majority of "possessed" patients.

Annual Reports to the Membership

The following are edited versions of the annual reports by the APA Secretary, Treasurer, Medical Director, Speaker, and Speaker-Elect and the chairpersons of the APA Committee on Constitution and Bylaws, Committee on Membership, and Committee of Tellers. The reports were presented at the APA annual business meeting in Washington, D.C., on May 3, 1992.

Report of the Secretary: Summary of Actions of the Board of Trustees, May 1991–March 1992

Steven S. Sharfstein, M.D.

OVERVIEW

It is my personal and constitutional privilege as Secretary to report to the membership the actions taken by the Board of Trustees and some of the significant activities of the Association over the past year. A more specific summary of Board of Trustees actions follows this overview. Over the past year the Board addressed a variety of economic issues and concerns, including problems in managed care systems, rising health care costs, and governmental efforts (local, state, and national) to regulate or change health care systems.

Membership

Membership activity and fiscal policies. The total membership as of April 1, 1992, was 37,512, which is 1% higher than last year. While Members-in-Training continue to be the greatest source of General Members, the number of medical students entering psychiatry residencies has stabilized, and thus the overall increase in APA membership has flattened. The proportion of Members-in-Training within the APA membership increased from 6% in January 1980 to 15.8% in 1992. Residents are significantly involved in the activities and components of the Association, including having a voting and a nonvoting member on the Board of Trustees and a representative and deputy representative from each of the seven Area councils within the Assembly. In addition, the Committee of Residents and Fellows and the resident fellowship programs have representation on the Board. The Committee of Early Career Psychiatrists focuses on the needs and interests of psychiatrists who have just completed their residencies.

In 1990 an ad hoc committee on membership and fiscal policies predicted a slower rate of growth of income from member dues, attributing this decrease primarily to the rapid growth in the number of members who would become dues exempt. Under the "rule of 95" a member reaches Life status when the member's age and number of years of membership total 95. To date, reaching Life status has been equivalent to becoming dues exempt. This spring APA members approved an amendment on the 1992 ballot that modifies the dues-exempt status so that members who achieve Life status in 1993 and thereafter will be required to pay reduced dues for 10 additional years. Life Members/Fellows will be billed for two-thirds of the highest dues

rate for the first 5 years after they achieve Life status and one-third of the highest dues rate in the succeeding 5 years. Thereafter, Life Members/Fellows will be exempt from dues payments. In addition to recommending this modification in dues-exempt status, the ad hoc committee recommended that APA offer members the option of paying dues in a lump sum (i.e., paying the full amount of dues that they would have paid over the remaining years of their dues-paying status). After the Budget Committee and the Committee on Membership delineated fiscal and administrative details for enacting such a plan, the Board approved this recommendation.

Membership directory. In February 1992 a subcommittee of the Committee on Membership met to explore issues related to publishing a membership directory. The subcommittee explored various options for conducting a survey that would obtain the needed information. The subcommittee agreed that a new membership directory (not a biographical directory) was needed by no later than 1994. The Board approved producing the directory and authorized the Committee on Membership to develop a budget and seek outside funding for the project.

Member benefits. The APA Purchasing Group, Inc., continues to enhance its ability to monitor and control APA-sponsored insurance programs. Through careful management and innovation, it has been able to hold the line on malpractice premiums: the APA-sponsored professional liability insurance program announced lower premiums for many policyholders for the 1992–1993 policy year. The rates for program participants decreased about 2% on average. Important modifications were made to the experience rating program, introduced last year and designed to offset the effects of adverse selection (in which the members with the lowest risk abandon the program for less expensive, competing policies, leaving the APA-sponsored program with higher average losses and fewer insureds, who then must pay higher premiums). Responding to member concerns about the threshold for determining what is a significant claim, the APA Purchasing Group agreed that regional variability of suit cost is important and took action to replace the nationwide \$20,000 threshold for defining significance. The thresholds for the 1992–1993 year are tied to premium level, which varies from \$20,000 to \$50,000, depending on location. The APA Purchasing Group will continue to study the effect of previous claims on future losses to evaluate the impact of the experience rating system on the program in the long term.

In recognition of the loss experience of the past 5 years and changes in program enrollment, rates were reduced in a number of states. Premiums remained at 1991-1992 levels in 28 states and fell in 20 states and the District of Columbia. California members' premiums are based on a new regional rating system; some California members' premiums have remained at the 1991-1992 level, while others have decreased from 14% to 48%, depending on rating district. Only one state, Texas, has seen higher rates in the 1992-1993 policy year, increasing either 5% or 15%, depending on locale.

Participation in APA's catastrophic health insurance program continues to fall. The basic premium was increased by 30% for the 1992-1993 policy year, mirroring the experience of most commercial health insurance programs. The Committee on Member Life, Accident, and Health Insurance continues its careful review of the performance of the catastrophic health insurance program to determine what changes may be warranted. In November 1991 many participants in the APA-sponsored disability and life insurance program received premium refunds. The refunds, based on effective date of coverage and amount of insurance, were due to the favorable loss experience of the disability and life insurance program.

APA/district branch activity. Traditionally, APA components and staff interact with the district branches, supporting their membership and governance efforts and working through the public affairs and legislative networks. This past year the Board gave considerable attention to the potential district branch expenses of covering the deductible of the directors and officers insurance. APA carries directors and officers insurance for the national society and for the district branches and state societies and assumes the deductible (\$200,000) for all ethics activities. The Board extended its assumption of the deductible in claims against its district branches and state societies arising out of actions affecting membership status or other activities undertaken at the written request or direction of APA. In addition, the Board approved an APA/district branch cost-sharing plan for paying additional portions of the deductible in cases that are not covered by any other arrangements; the cost-sharing plan incorporates a flat fee plus a differential based on the size of the district branch.

Ethics

The Ethics Committee continues to provide educational programs to assist district branches with the new procedures for handling complaints of unethical conduct that were implemented in October 1989. In 1990-1991 an ad hoc committee reviewed the composition and procedures of the Ethics Appeal Board, reporting to the Assembly in May 1991 and to the Board in September 1991. The Board approved a change in the composition and tenure of the Ethics Appeal Board, which will provide greater interaction among district branches and the appeals process, as well as greater flexibility for the President in making appointments to the Ethics Appeal Board.

In March 1992 the Board recommended development of an amendment to the APA Constitution and Bylaws regarding members who resign during ethics complaints, and it asked the Committee on Constitution and Bylaws to prepare wording for the amendment. An amendment to the Bylaws will be read to the membership at this annual business meeting for placement on the 1993 ballot. The amendment will permit APA to report to the membership and the National Practitioner Data Bank the name of a member against whom an ethics complaint is filed within 90 days of his or her resignation.

Public Affairs

APA's "Let's Talk About Mental Illnesses" campaign moved into its 5th year, continuing to reach millions of Americans with positive messages about mental illnesses and the effectiveness of psychiatric diagnosis and treatment. The film, workshop, and exhibit components of the campaign were supported by an unrestricted educational grant from the Upjohn Company. The three films (on panic disorder, anxiety disorder, and depression) have been seen 98.5 million times through direct APA distribution, distribution by Modern Talking Pictures, and through local and national television broadcast. The third film, "Depression: The Storm Within," won a CINE Golden Eagle Award, the most prestigious award for a documentary next to an Oscar, from the Council on International Nontheatrical Events. The

film is now eligible for entry in international film festivals and in the Academy Awards. The campaign's prize-winning workshop "Panic Disorder: Diagnosis, Treatment, and Management" has benefited 21,210 physicians and other health professionals, and the Division of Public Affairs' exhibits have been seen by 234,000 health professionals at 57 national meetings. During the year the Division of Public Affairs published new mental illness awareness guides for the media and health professionals (similar to earlier guides for clergy and educators). Wide distribution of the media guide was made possible through a much-appreciated grant from the American Psychiatric Foundation.

Joint Public Affairs and Government Relations Activities

Mental Illness Awareness Week. Each year the APA Division of Government Relations, with the help of the membership, contacts members of Congress to press for legislation in recognition of Mental Illness Awareness Week. In 1991 APA initiated the week (October 6-12) by hosting a breakfast on Capitol Hill, jointly convened with the newly formed Congressional Task Force on Mental Illness. The featured speakers included former Houston Oilers and National Football League Hall of Fame running back, Earl Campbell, who spoke of his personal experiences with panic disorder, and Dr. Freda Lewis-Hall, who spoke on psychiatric treatment of panic disorder. Almost all of district branches sponsored activities commemorating Mental Illness Awareness Week, during which APA sponsored a successful National Depression Screening Day, organized by Dr. Douglas Jacobs of Harvard University. Screening days were held at more than 100 sites in all 50 states, attracting over 5,000 participants (50% of whom were recommended for follow-up). Currently APA is working with Senator Paul Simon and Representative Ron Wyden to obtain introduction of the 1992 Mental Illness Awareness Week resolution in the Senate and House of Representatives.

Joint State Legislative and Public Affairs Institute. APA produced the first Joint State Legislative and Public Affairs Institute, held in Bal Harbour, Fla., Feb. 27 to March 1. The 4-day program attracted over 400 APA members, APA Auxiliary members, district branch executives, lobbyists, public affairs consultants, guests, and spouses. Participants represented 69 of the 76 district branches. The topics covered during the institute included managed care, access to care, nonphysician prescribing, media relations, and *Physicians' Current Procedural Terminology* (CPT) codes. In addition to learning of innovative developments around the country, the participants were instructed on lobbying strategy and media skills for more effective advocacy. The participants overwhelmingly urged continuation of the joint institute.

Government Relations

Many key issues for psychiatrists and patients were addressed throughout the past year. Highlights of some of the issues follow.

Access to health care. The Board of Trustees gave considerable attention to access issues. The prospects for health care reform are more confused and perhaps more remote in the short term than ever. President Bush joined the debate on health care reform by unveiling his own set of proposals, focusing chiefly on reform of the health insurance market. The Senate approved similar reforms as part of a larger tax and economic recovery bill; those health care reform provisions were, however, stripped from the tax bill in conference with the House of Representatives and deferred for possible consideration later as separate legislation. APA continues efforts to work with Congressional committees to improve coverage of treatment for mental disorders in all health care reform legislation. APA has managed to ensure that most of the key proposals for health care reform include at least some coverage of psychiatric services, although typically limited in scope and duration (primarily because of perceptions that coverage of psychotherapy and counseling is not a basic necessity or a medically necessary service). Comprehensive health care reforms may still be several years away.

Reorganization of and appropriations for the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA). The Board discussed Senate-approved legislation to reorganize ADAMHA, shifting the three institutes' research activities to the National Institutes of

Health while maintaining a separate services agency (Alcohol, Drug Abuse, and Mental Health Services Administration). In June 1991 the Board agreed to not support the reorganization of ADAMHA until it had consulted with other constituency groups. In December the Board continued to have serious reservations about the proposed reorganization, pledging to work to ensure that any outcome would be in the best interests of the mentally ill.

International medical graduates (IMGs). APA worked with the American Medical Association (AMA) in persuading both houses of Congress to pass legislation that, when implemented, will establish the AMA National Credentialing Verification Service as a repository for medical education and residency records. The legislation provides long-sought protection against discrimination against IMGs, as well as the assurance that patients will receive medical treatment from qualified and licensed physicians. The bills are fairly similar: they call for a federal study to determine whether IMGs experience higher rejection rates and longer waits for medical licensure. Both bills would provisionally recognize the AMA's new National Credentialing Verification Service as a way for IMGs to reduce the extra paperwork for licensure and hospital privileges. Although legislation has passed both the House and Senate, the date of the conference has not yet been set.

"Medigap" insurance regulations. APA efforts produced a major victory by ensuring that Medicare supplemental ("Medigap") insurance plans cover the current 50% beneficiary copayment for Medicare outpatient mental health treatment. The Omnibus Budget Reconciliation Act 1990 budget bill required the National Association of Insurance Commissioners to substantially revise its model regulation for Medigap insurance. APA has been pressing the Congress since August 1990, and the National Association of Insurance Commissioners since the spring of 1991, to make certain that the revisions explicitly require all Medigap policies to cover the full amount of the 50% beneficiary copayment for outpatient mental health care under Medicare. The National Association of Insurance Commissioners recently confirmed to APA that its revised model regulation does include such a coverage requirement.

Medicare fee schedule. In June 1991 APA was shocked and disappointed when the Health Care Financing Administration (HCFA) released its long-awaited proposal for a resource-based relative value scale (RBRVS); the drastic cuts were in stark contrast to what had been forecasted by the Hsiao team at Harvard University. While the cuts were of concern to all of medicine, they had a particular impact on psychiatry. APA responded to specific problems in the HCFA's initial proposal for the Medicare fee schedule. Before releasing the RBRVS Medicare fee schedule in late November, the HCFA increased the work relative value units for psychiatric services. While this change substantially improved the fees for psychiatric services over those originally proposed in June, the Board recognized that the overall impact on psychiatrists' fees, particularly for those practicing in high-cost urban areas, would be negative. APA is continuing to respond to the outpouring of concern from psychiatrists.

Psychologist hospital and prescribing privileges. The first group of clinical psychologists will soon enter their second year of training under the U.S. Department of Defense demonstration program for psychologist prescribing privileges training. They will not be permitted to prescribe independently. APA learned that some of the psychologists in the program were faring so poorly on the examinations for their courses that they asked to be permitted to audit the courses rather than receive specific grades. APA is now working with concerned members of Congress to call attention to this development and to press Department of Defense officials for a full explanation. With the vigorous support of the California and Texas district branches, APA helped persuade the Senate not to approve a bill that would have amended the Medicare part A conditions of hospital participation to permit clinical psychologists to care for inpatients receiving qualified psychologist services. At the state level, legislation on psychologist hospital privileges has been under consideration in 10 states. In 1991 Ohio enacted legislation that permits psychologists to be on hospital staffs but prohibits their having admitting privileges.

Student indebtedness. Although no final action was taken in 1991, the House Education and Labor Committee and the Senate Labor and Human Resources Committee each approved legislation that included provisions to end the current 2-year deferment of repayment of stu-

dent loans by medical residents. Both bills would provide residents with forbearance on their loans, but such loans would continue to accrue additional interest during the forbearance period. It is not possible to predict what the final conference product will be, and informed sources say that the bill may be almost entirely rewritten in conference. APA, with strong support from its Members-in-Training, continues an aggressive lobbying effort to restore the deferment.

Economic Affairs and Practice Activities

Managed care. Issues related to managed care have been discussed widely throughout APA over the past year. Members used the toll-free "hot line" to help identify egregious practices. Well-documented cases, as well as generic issues, were and are being discussed with the leaders of a number of utilization management companies. These meetings are convened under the auspices of the Committee on Managed Care within the Council on Economic Affairs. This communication has included dialogue with a major employer, which has accepted most of APA's comments on broad guidelines for utilization review for its employees. As recommended by the Assembly, the Board also adopted guidelines to be used when APA reviews industry criteria for standards of care.

During 1991-1992 APA has developed a number of documents related to managed care. The Committee on Managed Care published *Utilization Management: A Handbook for Psychiatrists*, which is being distributed on request through the 76 district branches. APA also published a new *Manual for Psychiatric Quality Assurance*, which includes a historical overview of APA's efforts to ensure appropriate care for patients. The Conference on Ethics for Psychiatry in Managed Care, sponsored by the Ethics Committee and the Committee on Managed Care, was held in October 1991. The conference probed the ethical dilemmas psychiatrists face as health insurers intensify efforts to manage mental health care benefits. The conference proceedings are being edited for publication.

Broader ethical issues in the delivery of psychiatric services are being studied by the ethics, managed care, and other committees. The Board did not endorse guidelines developed by the National Association of Private Psychiatric Hospitals. The Board directed APA to develop its own criteria for psychiatrists working in both public and private organized systems of care and, in March 1992, approved hospital admission procedures for psychiatrists.

For more than a year an Assembly ad hoc task force on managed care gathered information about membership support around the country for a variety of strategies to cope with problems found in managed care systems. In addition to geographic representation, the task force included minority and younger members to ensure incorporating their views. A preliminary task force report, first discussed by district branches, was considered by the Assembly in November 1991. In December 1991 the Board adopted the four types of strategies identified by the task force and endorsed by the Assembly: 1) legislative/regulatory, 2) market force influence, 3) consultative, and 4) judicial. APA is currently involved in the first three strategies, and district branches are engaged in legislative and regulatory matters. The Board asked the Committee on Managed Care to study and make recommendations about the specific proposals in the Assembly task force report.

A managed care network, similar to the public affairs and legislative networks, is being developed and will meet during the 1992 annual meeting. Each district branch has been asked to inform the APA Office of Economic Affairs of its local contact for the network. The Connecticut Psychiatric Society had, through voluntary contributions, collected over \$25,500, which it donated to APA for a litigation effort. Since APA apparently would not be using these funds for this specific purpose in the near future, the Board voted to return the money with its deep appreciation. The Board also expressed its appreciation to the Assembly for its considerable efforts in determining membership opinion and for its excellent report on recommended APA strategies with respect to handling problems in the managed care arena.

CPT-4. The Work Group on Codes and Reimbursements and the Office of Economic Affairs have worked to educate the membership about the newly established evaluation and management codes published in CPT-4 and about other significant changes in Medicare re-

imbursement. Several workshops have been presented around the country by Drs. Chester Schmidt and Tracy Gordy. Additionally, a workshop and a course will be presented at the 1992 annual meeting. A letter was sent to the nation's major insurers explaining the new interactive psychiatric medical codes, with explanations and examples of their use. Sample psychiatric vignettes, representing the new codes for inpatient and outpatient visits, have been made available to members. The Work Group on Codes and Reimbursements and the Office of Economic Affairs have continued to monitor the difficulties and concerns of members in regard to the new codes, with special emphasis on reimbursement by Medicare.

Research

DSM-IV. Work on *DSM-IV* continued at a strong pace. Draft criteria for each proposed diagnostic category were developed and distributed widely for comment in *DSM-IV, Work in Progress: Options Book*. A series of columns on *DSM-IV* were published in the *Hospital and Community Psychiatry* journal. Numerous activities related to *DSM-IV* are planned for this annual meeting, and field trials are being completed to assess specific nosologic issues. The National Institute of Mental Health is sponsoring a major meeting on *DSM-IV* and *ICD-10* in July 1992.

During the November 1991 Assembly APA received notice of a petition asking APA to hold a referendum on adopting *ICD-10*, after its publication, as the official psychiatric classification system in the United States and delaying the publication of *DSM-IV* at least until 1997. The petition fell short of the requisite 500 signatures of voting members, but the petitioners may resubmit a petition for a referendum on this issue for the 1993 ballot. In March 1992 the Board of Trustees affirmed the policy that signatures on a petition are valid only for the year in which the petition is initially submitted, and the Board stated that the petitioners must resubmit a new petition with the requisite number of current signatures if they wish the referendum to be on the ballot in the 1993 election.

Practice guidelines. Under the aegis of the APA Steering Committee on Practice Guidelines, practice guidelines are being drafted by psychiatrists in active clinical practice and are circulated for comments before coming to the Assembly and Board for approval. Two practice guidelines (for eating disorders and major depression) are in the final stages of consideration, and six others are in earlier stages of development. As a member of the AMA/Specialty Society Practice Parameters Partnership, APA has participated in developing criteria for practice guidelines for all of medicine. APA has also participated in an Institute of Medicine field testing of a preliminary guideline instrument. In May and June 1992 the Assembly and the Board will be considering for approval the APA-developed practice guidelines for eating disorders. Members are encouraged to participate in the development of these guidelines.

American Psychiatric Foundation, Inc.

Since its incorporation in 1990, the American Psychiatric Foundation, Inc., has continued to enhance the fund-raising objectives of the Association. The members of the Foundation's interim Board of Directors are Drs. Elissa P. Benedek (President), Carolyn B. Robinowitz (Executive Vice President), Mary Jane England (Secretary/Treasurer), Robert S. Garber, Edward Hanin, Lawrence Hartmann, Clifford Parish, Jr., G. Thomas Pfafchler, Howard Wallach, and Melvin Sabshin (ex officio). The organizational steps that have been taken include finalizing the application for recognition as a tax-exempt organization, which outlines activities the foundation may pursue in public education, research, professional development, and special projects. In addition, a business plan detailing programs and funding for the foundation has also been prepared. Corporate constituents are being invited to participate in the new Corporate Advisory Council. To date, the foundation has made contributions to the National Museum of Health and Medicine (\$10,000), the APA Division of Public Affairs for Mental Illness Awareness Week (\$10,000), the APA Library for automation of the card catalogue (\$16,000) and for reference acquisitions (\$3,000), the Manhattan Homeless Project (\$5,000), and the APA Award for Research (\$2,500/year, as seed money, for 5 years). The APA Board of Trustees approved expanding membership solicitation activities from primarily APA Life Members and Life Fellows to all APA members.

Conclusion

Every member of APA is welcome to attend meetings of APA components (except meetings of the Ethics Committee and Ethics Appeals Board or when a component goes into executive session). Your strong support is deeply appreciated; your recommendations for consideration by the Board or other components are most welcome.

Thank you for the privilege and honor of serving as your Secretary for the past year. I look forward to working with you to meet the challenges we face and opportunities we have during the coming year.

SUMMARY OF ACTIONS

The actions of the Board of Trustees are grouped by topic, and the topics are arranged alphabetically. The date of each action is given in parentheses at the end of the action. Complete wording and discussion of actions can be found in the minutes of the Board of Trustees.

Addiction

1. Approved the "Position Statement on the Care of Pregnant and Newly Delivered Women Addicts" (1) (approved by the Assembly in November 1991) (June 1991).
2. Authorized the Council on Addiction Psychiatry to explore the possibility of APA participation in the National Training System's initiative for a continuing education training project for psychiatrists that would focus on prevention and early identification of alcohol and other drug abuse problems (June 1991).
3. Adopted an APA policy against tobacco use and in support of voluntary discontinuation (June 1991).

Aging

1. Approved the report of the Task Force on Ethnic Minority Elderly for publication as part of the APA task force report series, subsequently discharging the task force and establishing the five-member Committee on Ethnic Minority Elderly within the Council on Aging (June 1991).
2. Approved the "Position Statement on Medical Use of Psychotherapeutic Medications in the Nursing Home" (Dec. 1991).

AIDS

1. Voted to promote the policy that a history of substance abuse should not preclude adequate treatment of substantial physical pain in AIDS patients (Dec. 1991).
2. Approved, as an official APA policy, a statement on HIV infection and impairment of personal, social, or occupational functions (approved by the Assembly in November 1991) (June 1991).
3. Adopted as APA policy the revised "AIDS Policy: Guidelines for Inpatient Psychiatric Units" (2) (Dec. 1991).
4. Adopted as APA policy the revised "AIDS Policy: Guidelines for Outpatient Psychiatric Services" (3) (Dec. 1991).
5. Voted to adopt as APA policy, subject to approval by the Assembly, the revised "AIDS Policy: Position Statement on HIV Infection" (Dec. 1991).
6. Adopted as APA policy, subject to approval by the Assembly, the revised "AIDS Policy: Position Statement on HIV and Discrimination" (Dec. 1991).

American Board of Psychiatry and Neurology

1. Approved the nomination of Dr. Lenore Terr for a second 4-year term on the Board of Directors of the American Board of Psychiatry and Neurology (ABPN), beginning January 1992 (June 1991).
2. Voted to forward the names of Drs. Elizabeth Weller, John Kemph, and Barry Nurcombe to the ABPN as the APA nominees for members of the ABPN Committee on Child Psychiatry (Dec. 1991).

American Journal of Psychiatry

1. Extended the tenure of three Associate Editors whose terms were completed in May 1992 (two of whom were eligible for reappointment) to permit the new Editor of the *Journal* to recommend (re)appointments (March 1992).

American Medical Association

1. Authorized APA's participation in the AMA Specialty Society Process to Develop Relative Values for New or Revised CPT Codes (May 1991).

2. Endorsed the AMA Coalition of Physicians Against Family Violence, authorizing the President to appoint APA representatives to the coalition, as requested, and agreeing to support the costs of sending these representatives to the meetings (March 1992).

3. Endorsed the AMA position on managed care (Dec. 1991).

4. Approved an APA resolution asking that the AMA Young Physicians Section consider a change in the current bylaws that would replace the term "young physicians" with "physicians recently completing residency or fellowship training" (Dec. 1991).

American Psychiatric Foundation

1. Ratified the Executive Action taken by the President, Speaker, and Dr. Carolyn Robinowitz, Acting Medical Director, to appoint Mr. Clifford Parrish, Jr., to serve on the Board of Directors of the American Psychiatric Foundation, Inc. (Dec. 1991).

2. Voted to allocate the following monies from contributions to the American Psychiatric Foundation: a) up to \$16,000 to the APA Library for the automation of reference sources and development of an on-line card catalogue system (from the Fund for the Future), b) \$10,000 to fund the production and distribution of the Mental Illness Awareness Week literature (from the Fund for the Future), and c) \$3,000 for APA Library reference acquisitions (from the APA Tribute Fund) (Sept. 1991).

3. Endorsed the following allocations by the American Psychiatric Foundation: a) \$5,000 to assist with program costs of the Manhattan Homeless Project and b) \$500/year for 5 years to the APA Award for Research in Psychiatry to serve as a monetary expression of support (March 1992).

4. Voted in principle that past and future contributions to the APA Pooled Income Fund should be designated for the sole benefit of the American Psychiatric Foundation (March 1992).

5. Authorized the American Psychiatric Foundation to accept \$25,000 from the Sarnat family to support the 1992 Rhoda and Bernard Sarnat Mental Health Award, to be given in recognition of significant and far-reaching contributions to the advancement of mental health by an individual, group, or organization, without regard for professional discipline or nationality (June 1991).

6. Voted to release to the American Psychiatric Foundation the list of current annual meeting exhibitors to permit solicitation of them into the Corporate Partners program (Sept. 1991).

7. Approved a solicitation of APA members by including a check-off box for voluntary contributions on all member dues statements, with the understanding that this mechanism would be reviewed within a year of implementation to determine its impact (March 1992).

American Psychiatric Press

1. Approved the reappointment of Dr. Doyle Carson and the appointment of Dr. Lawrence Hartmann to 4-year terms on the Board of Directors of the American Psychiatric Press, Inc. (APPI) (May 1991).

2. Authorized the Medical Director to terminate APA's contract with Martin Publishing, which produces "Dialogue," if and when it seems appropriate, in view of APPI's negotiations to produce and market a newsletter for laypersons (March 1992).

Annual Meeting

1. Approved accepting outside support from a pharmaceutical company to provide box lunches for participants in a course on com-

munity resources for the homeless scheduled for the 1992 annual meeting (March 1992).

2. Increased the fee for industry-sponsored symposia at annual meetings from \$25,000 to \$30,000, beginning with the 1993 annual meeting (Dec. 1991).

3. Extended the application of the revised guidelines for pharmaceutical or other industry-sponsored symposia to the Institute on Hospital and Community Psychiatry, beginning with the 1992 institute; further, voted that all requests for revisions to the guidelines must be referred to the Committee on Advertisers and Exhibitors and be made in conjunction with the program committees for both the annual meeting and the H&CP institute (Sept. 1991).

4. Authorized the Committee on Psychological Aspects of Nuclear Issues to seek outside funds, following established procedures and working in conjunction with the Medical Director's office, to cover travel expenses for five guest speakers for a symposium at the 1993 annual meeting (Dec. 1991).

5. Authorized Dr. Herbert Sacks to seek outside funding, following established procedures and working in conjunction with the Medical Director's office, to support travel expenses of speakers and an honorarium for one speaker who will participate in the symposium "Anne Sexton, Poet and Patient" at the 1992 annual meeting (March 1992).

6. Authorized the Consortium on Public Psychiatry to seek outside funding, following established procedures and working in conjunction with the Medical Director's office, from the National Institute of Mental Health (NIMH) to sponsor a workshop at the 1992 annual meeting, jointly planned by the consortium, NIMH, and the National Alliance for the Mentally Ill, that would focus on improving psychiatric services in public programs (Sept. 1991).

7. Authorized APA to receive funding from NIMH (approximately \$3,000) to cover the costs of setting up a meeting of mental health services researchers to be held during the 1992 annual meeting (Sept. 1991).

8. Voted to suspend (commencing with the 1992 annual meeting) the solicitation and display of scientific exhibits at annual meetings and H&CP institutes (Sept. 1991).

9. Approved the following policy for selection of APA meeting sites: APA will consider any significant conflict between a state's laws or policies and corresponding policies/positions of APA, and APA's policy positions will be weighed in making these decisions; further, agreed that if APA decides to meet in a restrictive state (e.g., anti-choice), APA will consider constructive ways to educate the public and to advocate for APA's position during the meeting (June 1991).

10. Approved holding APA annual meetings at the following sites: Miami in 1995, New York City in 1996, San Diego in 1997, and Toronto in 1998; further, voted to encourage Mr. George Campbell, Director of the Office of Meetings Management, to report to the Board in December 1991 or March 1992 additional suggested sites for future annual meetings (Sept. 1991).

11. Authorized the Committee on Women, following established procedures and working in conjunction with the Medical Director's office, to seek outside funding of approximately \$10,000 to support a women's activity center at the 1992 annual meeting (June 1991).

12. Authorized the Committee on International Medical Graduates to seek approximately \$5,000 in outside funding, following established procedures and working in conjunction with the Medical Director's office, to support a reception for young international medical graduates and leaders of various ethnic groups at the 1992 annual meeting (Dec. 1991).

13. Authorized the Committee of Young Psychiatrists to seek outside funding (approximately \$12,000), following established procedures and working in conjunction with the Medical Director's office, to support a roundtable session for young psychiatrists at the 1992 annual meeting (Dec. 1991).

Awards

1. Authorized the Committee of Asian-American Psychiatrists, following established procedures and working in conjunction with the Medical Director's office, to seek outside funding of \$7,500 to sponsor a reception in honor of Dr. Kun-Po Soo at the 1992 annual meeting, with the understanding that the conditions for receipt of the funding must be consistent with APA policy (June 1991).

2. Authorized publication of a brochure publicizing the Asian/Asian-American Award (Dec. 1991).
3. Authorized the Committee on History and Library, following established procedures and working in conjunction with the Medical Director's office, to seek approximately \$7,000 in outside funding to support the Benjamin Rush Lectureship (June 1991).
4. Approved the following recipients of the APA Distinguished Service Awards to be presented at the 1992 annual meeting: Drs. Eli Robins and Albert J. Solnit for the individual awards and the Carters' Habitat for Living for the institutional award (providing that either or both of Jimmy and Rosalyn Carter could attend the annual meeting to receive the award) (Dec. 1991).
5. Ratified an Executive Action taken by the President, Speaker, and Medical Director to approve the American College of Neuropsychopharmacology as a recipient of the 1992 APA institutional Distinguished Service Award (March 1992).
6. Approved changing the description of the Human Rights Award to include "from any country" after the words "predominantly humanitarian or professional ones" and to authorize presentation of the award in 1992 (June 1991).
7. Approved the establishment of the William Sorum Award (June 1991).

Components—Discharged

1. *Board of Trustees components*: Ad Hoc Committee on the Annual Business Meeting and Forum (June 1991); Ad Hoc Task Force on Conflicts of Interest (March 1992); Ad Hoc Committee to Develop a Slate of Candidates for Election to the ABPN (June 1991); Ad Hoc Committee on Managed Care Issues (June 1991); Ad Hoc Committee to Revise Procedures for Nominating the MITTE (June 1991).
2. *Council on Aging*: Task Force on Ethnic Minority Elderly (June 1991).
3. *Council on International Affairs*: Task Force on APA Liaison With the World Psychiatric Association (Dec. 1991).
4. *Council on Medical Education and Career Development*: Task Force on Post-Residency Fellowship Training Programs (June 1991).
5. *Council on Psychiatry and Law*: Task Force on Disclosure of Psychiatric Treatment Records in Child Custody Disputes (Dec. 1991).
6. *Council on Research*: Task Force on Tardive Dyskinesia (Dec. 1991); Task Force on Quantitative Electrophysiological Assessment (Dec. 1991).

Components—Established

1. *Board of Trustees components*: Ad Hoc Committee on APA Legal Representation (June 1991); Ad Hoc Committee to Develop a Slate of Candidates for Election to the ABPN (Dec. 1991); Ad Hoc Committee on Membership Losses (June 1991); Ad Hoc Committee to Review the Ethics Appeals Board (this is a joint Board of Trustees and Assembly component to review the Ethics Appeals Board every 4 years, i.e., the first ad hoc committee would be appointed in 1994 for the 1995–1996 cycle) (Sept. 1991); Task Force to Review Medical Necessity and Reimbursement Criteria for Use by Managed Care Organizations and Payers of Psychiatric Care (joint Board of Trustees and Assembly component) (June 1991).
2. *Council on Addiction Psychiatry*: Task Force on Nicotine Dependence (Dec. 1991).
3. *Council on Aging*: Committee on Ethnic Minority Elderly (June 1991); Work Group on Model Standards for Long Term Care Insurance (established June 1991, funded Dec. 1991).
4. *Council on Medical Education and Career Development*: Work Group on Accreditation and Certification (Dec. 1991).
5. *Council on Psychiatry and Law*: Task Force on Peer Review of Psychiatric Testimony (Dec. 1991).

Components—Modified

1. *Constitutional components*: Established a subcomponent of the Committee on Membership to study the feasibility of producing a directory of members (Dec. 1991) and then authorized the subcomponent to produce a membership directory (March 1992).
2. *Special boards and commissions*: a) Approved 3-year staggered

tenures for members of the Commission on AIDS, with the understanding that each member could be reappointed once, and authorized annual appointment of the chairperson of the commission (June 1991); b) expanded the charge and membership of the Commission on Subspecialization to include liaison with the Committee on Graduate Education (within the Council on Medical Education and Career Development) and with the Residency Review Committee for Psychiatry of the Accreditation Council for Graduate Medical Education (June 1991 and Dec. 1991); c) changed the membership of the Ethics Appeals Board to include two past Presidents, a past Speaker of the Assembly, the chairperson of the Ethics Committee, and a chairperson of a district branch ethics committee, with the Secretary continuing as chairperson; tenure for members was set at 3 years, and it was requested that members selected to serve on the Ethics Appeals Board have had ethics committee experience (at either the local or national level) and be strongly committed to the ethics process (Sept. 1991).

3. *Council on Children, Adolescents, and Their Families*: Extended the tenure of the Task Force on Day Care for Preschool Children to December 1993 to permit the task force to monitor proposed day care legislation (Dec. 1991); transferred the Blanche F. Ittleson Award Board from the Council on Internal Organization to the Council on Children, Adolescents, and Their Families (Dec. 1991).

4. *Council on Economic Affairs*: Authorized the transfer of the Committee on Private Practice from the Council on Psychiatric Services to the Council on Economic Affairs, with the understanding that there would be liaison with the Council on Psychiatric Services (no change in the committee's charge) (March 1992).

5. *Council on Internal Organization*: Changed the name of the Foundations' Fund Prize to the APA Research Award (Dec. 1991); transferred the Blanche F. Ittleson Award Board to the Council on Children, Adolescents, and Their Families (Dec. 1991); transferred the Marie H. Eldredge Award Board to the Council on Psychiatric Services (Dec. 1991); changed the name of the Personnel Committee to the Committee on Human Resources (June 1991).

6. *Council on Medical Education and Career Development*: Expanded the charge of the Committee on Graduate Education to include responsibility for all future activities related to subspecialty fellowship training, in collaboration with the Commission on Subspecialization, and, further, to include liaison with the Commission on Subspecialization and conveyance of information regarding all applications for certification of added qualifications (June 1991 and Dec. 1991); changed the name of the Task Force on Educational Activities for Diagnostic Systems to the Task Force on Diagnostic Education (no change in the charge) (Dec. 1991); changed the name of the Committee of Young Psychiatrists to the Committee of Early Career Psychiatrists (no change in the charge) (Dec. 1991).

7. *Council on National Affairs*: Revised the charge to the Committee of Black Psychiatrists (Dec. 1991); changed the name of the Committee of American Indian and Alaskan Native Psychiatrists to the Committee of American Indian, Alaska Native, and Native Hawaiian Psychiatrists and authorized an addition to the membership of the committee to include a representative of Native Hawaiian psychiatrists (Dec. 1991).

8. *Council on Psychiatric Services*: a) Authorized the Council on Psychiatric Services in December 1990, by Board approval of an action paper from the Assembly, to establish a consortium on public psychiatry; by June 1991 the consortium included representatives from the Committee on Disability and Rehabilitation, the Committee of State and Community Psychiatry Systems, the Committee on Chronically Ill and Emotionally Handicapped Children, the Task Force on Geriatric Psychiatry in the Public Mental Health Sector, the Task Force on the Homeless Mentally Ill, the Assembly Committees on Public Psychiatry and on Community Psychiatry and the State/University Collaboration Project; in December 1991 the Board authorized inviting representatives from the following additional components to join the consortium on public psychiatry: the Committee on Veterans' Affairs, the Committee on Psychiatric Services in Jails and Prisons, the Committee on Psychiatric Services in the Military, the Committee on Psychiatric Services to the Mentally Retarded/Developmentally Disabled Persons, and the Assembly Committee of Representatives of Minority/Underrepresented Groups; b) expanded the charge of the Council on Psychiatric Services to permit it to directly

invite groups to join the consortium on public psychiatry as the council sees appropriate (Dec. 1991); transferred the Marie H. Eldredge Award Board from the Council on Internal Organization to the Council on Psychiatric Services (Dec. 1991); transferred the Committee on Private Practice from the Council on Psychiatric Services to the Council on Economic Affairs, with the understanding that there would be liaison with the Council on Psychiatric Services (no change in the charge) (March 1992).

Components—Renewed

1. All of the following were renewed for 1 year: Ad Hoc Task Force on Conflicts of Interest (June 1991); Ad Hoc Committee on Legislation Affecting Quality of Care (June 1991); Ad Hoc Committee on Liaison Activities (June 1991); Ad Hoc Committee to Plan for APA's Sesquicentennial (June 1991); Ad Hoc Committee for the Pilot Advocacy Project (June 1991).

Education

1. Authorized the Council on Medical Education and Career Development to further explore the feasibility of a policy that would require APA to sponsor programs (in addition to those at annual meetings and H&CP institutes) for members to help them prepare to take board examinations (Dec. 1991).

2. Affirmed that APA will follow the "Guidelines for Commercial Support of Continuing Medical Education," which recently were adopted by the Accreditation Council on Continuing Medical Education (Dec. 1991).

3. Voted to change APA's continuing medical education (CME) requirements to be consistent with recently revised AMA CME requirements (June 1991).

4. Postponed, until the March 1992 meeting of the Board, action on APA joint sponsorship of CME activities (Dec. 1991); further, deferred again any action regarding termination of APA joint sponsorship of CME activities, to enable further discussion with district branches (March 1992).

5. Accepted the report of the Task Force on Educational Activities for Diagnostic Systems (regarding the *DSM-III-R* Diagnostic Practice Survey) for appropriate use; further, voted to release the data to the authors of the report for their use in independently published articles (Dec. 1991).

6. Authorized the Task Force on Educational Activities for Diagnostic Systems to conduct a follow-up of an initial survey to collect data on psychiatrists' different cognitive styles and approaches to diagnosis in their use of *DSM-III-R* (Dec. 1991).

7. Authorized the Council on Medical Education and Career Development to convene a 1-day meeting consisting of six representatives (two each from APA, the ABPN, and the Residency Review Committee for Psychiatry) to address issues related to accreditation of subspecialty fellowship training programs and certification of individuals completing such programs (June 1991).

8. Voted to recommend to the Association of Directors of Medical Student Education Programs that each department of psychiatry identify a director of medical student education who will spend a significant portion of time addressing issues related to undergraduate medical education and recruitment of medical students into psychiatry; further, authorized the Council on Medical Education and Career Development to send a letter to the American Association of Chairmen of Departments of Psychiatry, enlisting the support of its members in addressing issues involving recruitment into psychiatry (Dec. 1991).

9. Voted to ask APA's representatives on the Residency Review Committee for Psychiatry to remind committee site visitors of issues involving compliance with the requirement for training in transcultural issues (Dec. 1991).

10. Approved the following slate of resident nominees to be considered for selection as resident representative by the Residency Review Committee for Psychiatry: Drs. Gerald Bunting Blake, Peter Della Bella, and David Hackney (March 1992).

11. Authorized the Committee on Residents and Fellows and the Council on Medical Education and Career Development, following established procedures and working in conjunction with the Medical

Director's office, to seek outside funding of approximately \$14,000 to support production and distribution of the *Psychiatric Residents' Newsletter* three times a year (June 1991).

12. Authorized the President or Medical Director to send a letter to the Residency Review Committee for Psychiatry, calling for an addition to the "Special Requirements for Residency Training in Psychiatry," stating that "programs must have a plan to foster the development of skills for those residents interested in conducting psychiatric research. This plan should include opportunities for conducting research under the supervision of a mentor and training in the principles and methods of research" (Dec. 1991).

13. Authorized the Medical Director to send letters to the American Association of Directors of Psychiatry Residency Training and the American Association of Chairmen of Departments of Psychiatry, asking for each organization's position on major issues related to subspecialty fellowship programs (Dec. 1991).

Elections

1. Authorized the results of the mail ballot in which the results of the 1991 election were accepted and the decision to dispose of the ballots was postponed until the Board meeting on May 12, 1991 (May 1991).

2. Authorized staff to destroy the ballots from the 1991 election immediately after the 1991 annual meeting (May 1991).

3. Accepted the results of the 1992 election and authorized staff to destroy the ballots from the election after the 1992 annual meeting (March 1992).

4. Changed the mailing date for the ballots from February 20 to February 5 and to approve appropriate changes to the "Operations Manual of the Board of Trustees" (June 1991).

5. Approved changes to section A.2.c. of "Election Procedures," in the operations manual appendix F-1, to read, "Biographies of candidates are limited to six items in seventy-five words (exactly)" (this is based on the word-counting method described in the report of the Elections Committee, using *Webster's Ninth New Collegiate Dictionary*, 1989 edition, as the standard) (June 1991).

6. Approved the addition of a paragraph (paragraph 3) to section II.E. of "Guidelines for Nomination and Elections," in the operations manual appendix F-2, and renumbering paragraphs II.E.3-7 as II.E.4-8; the new paragraph would end statements and answers to questions once the word count has been reached (June 1991).

7. Approved the addition of a paragraph (paragraph 4) to section II.A. of "Guidelines for Nomination and Elections," in operations manual appendix F-2, and renumbering paragraphs II.A.4-7 as II.A.5-8; the new paragraph would require candidates to include a summary of the guidelines in their letters to members who are asked to support them (June 1991).

8. Affirmed the policy that signatures on a petition are valid only for the year in which the petition is initially submitted and that petitioners are required to resubmit a new petition with the requisite number of current signatures if they wish the petition to be on the ballot in the next year's election (March 1992).

Ethics

1. Approved the following regarding the composition of the Ethics Appeals Board: a) the Secretary will continue to chair the Ethics Appeals Board, which will consist of five members (two past Presidents, a past Speaker of the Assembly, the chairperson of the Ethics Committee, and a chairperson of a district branch ethics committee); b) tenure for members will be extended to 3 years; c) members will be selected from those who have hands-on ethics committee experience at either the local or the national level and who are strongly committed to the ethics process (Sept. 1991).

2. Established an ad hoc committee, appointed on a 4-year cycle, to review the activities of the Ethics Appeals Board and to report to the Assembly and Board of Trustees (Sept. 1991).

3. Approved the policy that, at the time of an appeal, the appellant and his or her lawyer will be notified of the following four criteria for appeal and requested to answer a series of questions that identify which of the four criteria are being appealed: a) there have been procedural irregularities or deficiencies; b) *The Principles of Medical Eth-*

ics With Annotations Especially Applicable to Psychiatry have been improperly applied; c) there is no substantial evidence to justify the findings or sanction imposed by the district branch; or d) substantial new evidence brings into question the findings and conclusions of the district branch ethics committee (Sept. 1991).

Fiscal Issues

1. As reported out of executive session, voted to include funding (approximately \$3,000) in the 1992 APA budget for the Work Group on Model Standards for Private Long-Term Care Insurance (Dec. 1991).

2. Tentatively approved the \$25.4-million 1992 APA operating budget, noting that final approval of the budget would be given in December 1991 (Sept. 1991).

3. Approved the 1992 APA budget of approximately \$24.7 million, with the understanding that if the trend of declining revenue worsened during the year, additional reductions in the budget could be made (Dec. 1991).

4. Voted to ask the Treasurer, the chairperson of the Budget Committee, legal counsel, and a representative of APA's auditing firm to review current APA procedures for audit reporting to determine if there are any problems, concerns, or issues and to return to the Board with recommendations for any needed change (June 1991).

5. Authorized the execution of all documents necessary to implement fiscal transactions with American Security Bank, subject to approval of such documents by legal counsel (June 1991).

6. Established an account with First National Bank of Maryland, D.C. (March 1992).

7. Authorized deduction of \$3,000 from the budget allocation for managed care litigation and expenditure of this amount to support the newly formed Joint Assembly/Board Task Force to Review Medical Necessity and Reimbursement Criteria for Use by Managed Care Organizations and Payers of Psychiatric Care (June 1991).

8. Authorized use of the balance of unexpended monies in the 1991 Board of Trustees contingency fund (after all funds authorized for 1991 were spent as needed) as the Board contingency fund through the tenure of the current Board (May 1992); further, authorized making the 1992 Board contingency fund the 1992-1993 Board contingency fund (beginning with the tenure of the new Board), with the understanding that in the future the allocation of Board contingency fund monies would be synchronized with the tenure of the Board (i.e., from May to May) (Dec. 1991).

9. Authorized a member of the APA Consultation Service Board and another appropriate individual to make a short visit to Puerto Rico to clarify the nature of the assistance needed by Puerto Rico and to report to the Board of Trustees in May 1992; further, voted to allocate up to \$5,000 from the Board contingency fund to support this trip (March 1992).

10. Approved the 1992 membership dues structure, which incorporates a weighted aggregate increase of 4.4% (Sept. 1991).

11. Established a program whereby General Members or Fellows who are 40 or more years of age may pay a lump sum to the Association and shall not be required to pay further annual dues or assessments (to continue as members or Fellows of APA, such members must continue to meet all other requirements of membership, including ethical conduct and continuing medical education, and must remain members in good standing of a district branch of the Association; no refund of lump-sum dues payments shall be made for any reason, including death, disability, resignation, or expulsion from the Association) (June 1991).

12. Approved the amount of the required lump-sum dues payment through Dec. 31, 1991; further, authorized the option of making such a payment in two installments over a period not to exceed 15 months, provided that the member pays a 10% installment fee (10% of the second payment) (June 1991).

13. Voted to require staff and the Budget Committee to report annually to the Board of Trustees on the implementation of the lump-sum dues payment program, the number of members who have exercised this dues option, and the amounts from such lump-sum dues payments that are invested in the Continuing Dues Payment Fund and the Board Restricted Investment Fund (June 1991).

14. Authorized the Treasurer to establish a special fund, called the

Continuing Dues Payment Fund, into which a portion of each lump-sum dues payment shall be deposited at an amount to be determined by financial staff and from which, each year, an amount equal to the annual dues that the member would have paid will be transferred into the membership dues account (June 1991).

15. Authorized the Treasurer to establish a special fund to be called the Board Restricted Investment Fund, into which all receipts from lump-sum dues payments that are not deposited in the Continuing Dues Payment Fund shall be deposited (June 1991).

16. Authorized APA, after appropriate negotiation by the Medical Director, to accept \$150,000 per year for 3 years from Abbott Laboratories to support educational activities of the Association (June 1991).

17. With respect to financial planning, voted a) to establish a target for liquid reserves of 3 months of staff salaries; b) to request the chairperson of the Committee on Human Resources to attend meetings of the Budget Committee as a consultant; c) to terminate the Investment Advisory Committee with an expression of appreciation to its members for many years of valuable service; d) to require that all proposed capital expenditures be included in a capital budget submitted as part of the operating budget (Sept. 1991).

18. Authorized the Committee on History and Library, following established procedures and working in conjunction with the Medical Director's office, to seek outside funding (\$50,000-\$100,000) to construct a new rare books room within the APA Library (June 1991).

19. Authorized changing the line of mutual funds offered by the APA member retirement program to the Heritage line of mutual funds managed by Raymond James and Co. (June 1991).

20. Approved increasing the daily stipends for the President, President-Elect, Speaker, and Speaker-Elect to \$500/day or the proportionate amount per part day, to be applicable to all future billings (June 1991).

21. Approved changes to the plan document for the APA retirement savings plan (March 1992).

22. Authorized attempts to find continued funding for the State/University Collaboration Project and to consider establishing a presence or staff office within APA for this function (Dec. 1991).

23. Approved a new fiscal policy on member and staff travel reimbursement (Sept. 1991).

Forensic Psychiatry

1. Approved the "Position Statement on Peer Review of Expert Testimony" (approved by the Assembly in November 1991) but deferred action on the accompanying background document until the March 1992 Board meeting to permit concerned members of the Assembly to discuss it and offer further comments (Dec. 1991).

2. Accepted the revised resource document on peer review of expert testimony accompanying the "Position Statement on Peer Review of Expert Testimony," which was approved by the Assembly and the Board in November and December 1991, respectively (March 1992).

3. Approved the revised "Report of the Task Force on the Use and Misuse of Psychiatric Diagnoses in the Courts" for publication as an APA task force report (Dec. 1991).

4. Endorsed, as a resource document, "Right to Refuse Medication: Judicial Review Supplement" (Dec. 1991).

Governance

1. Approved the recommendation of the Committee on Constitution and Bylaws to approve an amendment to chapter 8.5 of the Bylaws for reading to the membership at the 1992 annual meeting and placement on the 1993 ballot; the amendment would ensure that a referendum which passes would have a majority of the votes (March 1992).

2. Referred to the Committee on Constitution and Bylaws a recommendation that the Bylaws be amended to permit reporting to the membership and the National Practitioners Data Bank the name of any member against whom an ethics complaint is filed within 90 days of his or her resignation (wording for the amendment approved by an Executive Action in April 1992 and scheduled for ratification at the May Board meeting) (March 1992).

3. Approved new procedures for implementing APA conflict of interest policy (March 1992).

4. Voted to distribute to the district branch and state association presidents the document "Fiduciary Responsibilities of Association Officers and Board of Trustees Members"; further, voted to use this document in the training of new officers, Board members, Assembly representatives, and district branch presidents-elect (Dec. 1991).

5. As reported out of executive session, was informed that the law firm of Onek, Klein, and Farr would become Klein, Farr, Smith, and Taranto as of June 28, 1991, and that senior partners Mr. Joe Onek and Ms. JoAnn Macbeth would be moving to the firm of Crowell and Moring; it was anticipated that Mr. Joel Klein could continue to provide services to APA through December 1991, and a small advisory committee of Drs. John McIntyre, Elissa Benedek, and Carolyn Robinowitz was appointed to discuss issues related to future APA legal representation (June 1991).

6. Voted to retain Ms. JoAnn Macbeth of the firm Crowell and Moring as general counsel and to authorize the Medical Director to enter into contract/fiscal negotiations with Ms. Macbeth and her firm for their services, reporting back to the Board in June (March 1992).

7. Approved specific arrangements for contracts with the editors of the three major APA periodicals, *American Journal of Psychiatry*, *Hospital and Community Psychiatry*, and *Psychiatric News*, including a 3-year contract for any new editor and, on the basis of a positive performance evaluation, renewal for two 5-year periods, with the understanding that each editor should serve no longer than 13 years as editor of one of these three periodicals (March 1992).

8. Authorized the Medical Director and the President to establish a component that will begin to develop evaluation criteria for the editors of the three major APA periodicals (March 1992).

9. Authorized Drs. Hartmann and English to implement a May 1988 action of the Board (i.e., to review and evaluate each editor of the major APA periodicals who is appointed by the Board of Trustees, in the third year of editorship and every 5 years thereafter) and then to return to the Board in June with a recommendation about offering contracts (renewable or not) to the existing editors (March 1992).

10. Approved the "Conflict of Interest" policy for inclusion in the APA personnel manual, with the understanding that the final version would be approved by general counsel (Dec. 1991).

11. Approved the "Code of Ethics" policy (subject to final approval by general counsel) for inclusion in the APA personnel manual (Dec. 1991).

12. Approved the "Drug-Free Workplace" policy (subject to final approval by general counsel) for inclusion in the APA personnel manual (Dec. 1991).

13. Approved the "Sexual Harassment" policy (subject to final approval by general counsel) for inclusion in the APA personnel manual (Dec. 1991).

14. Waived current policy to permit Dr. Kenneth Paul Rosenberg to be reappointed to serve an additional year (through May 1993) as a member and chairperson of the Subcommittee on Video of the Scientific Program Committee (Dec. 1991).

15. Waived the policy in the operations manual to permit reappointment of Dr. Jeremy Lazarus as member and chairperson of the Ethics Committee for 1 additional year (through May 1993) (March 1992).

16. Recommended to the Budget Committee that it continue support of efforts to resolve the member/manpower shortage of the Scientific Program Committee (June 1991).

17. Requested the Medical Director to search promptly for psychiatrists to direct APA's Office of National/Minority Affairs and Office of Education, asking him to report progress to the Board in December 1991 (Sept. 1991).

Government Relations

1. Voted not to support the reorganization of ADAMHA at this time, until APA has consulted with other constituency groups and until issuance of the forthcoming Institute of Medicine report on the federal government's organization for administering research and services (June 1991).

2. Voted "that APA continues to have serious reservations about the proposal to reorganize ADAMHA and that APA will work to

ensure that any outcome is in the best interests of the mentally ill of this country" (Sept. 1991).

3. Authorized APA's support of efforts at both the state and federal levels to ensure that adequate funding is made available for clozapine treatment and for appropriate monitoring of all patients for whom this medication is likely to be of significant benefit (Dec. 1991).

4. Authorized legal counsel to prepare an opinion on the legal aspects and feasibility of APA's challenging recent interpretations reported in the *Federal Register* that would forbid psychiatrists to code for hospital admission and individual psychotherapy on the same day (Dec. 1991).

5. Voted to support the HealthAmerica Act (S. 1227) introduced jointly by Senators George Mitchell (D-Maine), Edward Kennedy (D-Mass.), Jay Rockefeller (D-W.Va.), and Donald Riegle (D-Mich.) on June 5, 1991 (June 1991).

6. Reaffirmed its policy of urging state legislators and regulators to adopt the requirement that hospital admissions be limited to psychiatrists who adhere to the following criteria: a) every admission, voluntary or involuntary, must be clinically justified by the admitting psychiatrist; b) each patient admitted by a psychiatrist may be admitted only after he or she is evaluated face-to-face by the admitting psychiatrist who determines the necessity of the admission; and c) in an emergency, the admitting psychiatrist may order by telephone whatever measures are needed for the safety of the patient (the face-to-face evaluation should occur as soon as possible but no longer than 6 hours after an emergency admission) (this emergency provision excludes children under age 14, each of whom must be seen by a psychiatrist before admission) (March 1992).

7. Endorsed a joint public affairs/legislative affairs campaign to enact state legislation to regulate managed care in states that have not acted on such legislation (using a draft model state bill developed by the Joint Commission on Government Relations and the Division of Government Relations) (March 1992).

8. Authorized the Division of Government Relations, working with ADAMHA, the National Institutes of Health, and Congress, to advocate for a loan forgiveness program for individuals engaging in psychiatric research training programs (Dec. 1991).

9. Voted to support the Medical Substance Abuse Treatment Act of 1991, recognizing that treatment services should be covered in all appropriate settings under medical supervision (in addition to residential settings) (Dec. 1991).

10. Endorsed the "Statement on Vocational Rehabilitation for Persons With Disabilities" developed by the National Task Force on Rehabilitation and Employment of Persons with Psychiatric Disabilities, with the understanding that additional comments from the APA Committee on Disability and Rehabilitation would be forwarded to the national task force (March 1992).

11. Authorized APA to work for additional federal funding to support the Women and Alcohol Research Equity Act (June 1991).

Homelessness

1. Approved the report of the Task Force on the Homeless Mentally Ill for publication as a task force report (Dec. 1991).

Hospital and Community Psychiatry Journal

1. Approved the reappointment of Dr. Leonard Stein and the appointment of Drs. Jeffrey L. Geller and George M. Simpson to the H&CP Editorial Board (March 1992).

Hospitalization

1. Approved a resolution to support the following guidelines for psychiatrists who admit patients to hospitals: a) every admission, voluntary or involuntary, must be clinically justified by the admitting psychiatrist; b) each patient admitted by a psychiatrist may be admitted only after he or she is evaluated face-to-face by the admitting psychiatrist who determines the necessity of the admission; and c) in an emergency, the admitting psychiatrist may order by telephone whatever measures are needed for the safety of the patient (the face-to-face evaluation should occur as soon as possible but no longer than 6 hours after an emergency admission) (this emergency provision ex-

cludes children under age 14, each of whom must be seen by a psychiatrist before admission) (March 1992).

Institute on Hospital and Community Psychiatry

1. Authorized the Committee on Universal Access to Health Care to seek outside funding, following established procedures and working in conjunction with the Medical Director's office, to support travel expenses for speakers and discussants at the half-day workshop on universal access at the 1992 H&CP institute (March 1992).

2. Extended the application of the revised guidelines for pharmaceutical or other industry-sponsored symposia to the Institute on Hospital and Community Psychiatry, beginning with the 1992 institute; further, voted that all requests for revisions to the guidelines must be referred to the Committee on Advertisers and Exhibitors and be made in conjunction with the program committees for both the annual meeting and the institute (Sept. 1991).

3. Voted to suspend (commencing with the 1992 annual meeting) the solicitation and display of scientific exhibits at annual meetings and H&CP institutes (Sept. 1991).

4. Approved the following policy for selection of APA meeting sites: APA will consider any significant conflict between a state's laws or policies and corresponding policies/positions of APA, and APA's policy positions will be weighed in making these decisions; further, agreed that if APA decides to meet in a restrictive state (e.g., anti-choice), APA will consider constructive ways to educate the public and to advocate for APA's position during the meeting (June 1991).

Insurance Programs

1. Asked Mr. Joel Klein, APA legal counsel, Mr. Rich Feeley, APA insurance and financial consultant, Dr. Sabshin, and Dr. Robinowitz to prepare clearly worded options for any changes recommended in APA's policy of indemnification of district branch activities, with the understanding that APA currently indemnifies the district branches only for activities related to ethics (June 1991).

It was recommended that APA assume the deductible under its directors and officers insurance policy in claims against district branches and state societies, otherwise covered by insurance, arising out of a) actions affecting membership status or b) other actions or activities undertaken by the district branch or state society at the written request or direction of APA. After discussion, the Board voted to postpone consideration of this item until its December meeting, requesting the Budget Committee to prepare a financial impact statement (Sept. 1991).

2. Postponed until March 1992 any action and further discussion on the plan for extending APA's coverage of the cost of the deductible in the directors and officers insurance plan for district branches and state associations, with the understanding that the proposal (including fiscal implications and exactly what the Association would be covering) would be presented to the Board in writing (Dec. 1991).

3. Voted to assume the deductible under the APA directors and officers insurance policy in claims against district branches and state societies, otherwise covered by insurance, arising out of a) actions affecting membership status or b) other actions or activities undertaken by the district branch or state society at the written request or direction of APA (March 1992).

4. Approved a plan for cost sharing between APA and the district branches to cover the deductible of the directors and officers liability insurance in cases that are not covered by any other arrangement; the formula for this coverage is as follows: the district branch will assume \$2,000 plus \$40 per full-dues-paying member and a prorated amount for all other dues-paying members, based on their dues rates, and APA will assume the balance (March 1992).

5. Approved settlement in the lawsuit *Insurance Equities Corporation v. APA*, as recommended by legal counsel; further, authorized any officer of APA to execute the settlement agreement (Dec. 1991).

International Affairs

1. Authorized sending letters to the medical officers of health in the countries in the new Commonwealth of Independent States (former Soviet Union), indicating APA's appreciation of the extreme difficulties being faced, expressing APA's concern that the mentally ill are at

great risk of deprivation in hard times, asking the officials to ensure that supplies of food and medicine are provided to all psychiatric hospitals, and insisting that the victims of psychiatric abuses under the former Communist regime continue to receive the rehabilitation they require (March 1992).

2. Authorized sending a letter to the director of the Serbsky Psychiatric Institute in Moscow, urging her to express public concern about the use of confidential psychiatric records to denounce political figures and, moreover, the use of such records for any purpose not related to the subjects' best interests (March 1992).

3. Authorized the Committee on International Education to organize a series of roundtable symposia in Central and South America to discuss psychiatric educational curricula; authorized the committee to seek cosponsorship with the InterAmerican Council of Psychiatric Organizations; and authorized the committee to seek outside funding, following established procedures and working in conjunction with the Medical Director's office, to support this project (Dec. 1991).

4. Authorized the Committee on International Education to gather data and to produce an international directory of psychiatry, in conjunction with the Committee of Hispanic Psychiatrists, Committee of Asian-American Psychiatrists, and Committee on International Medical Graduates and with the AMA, the Educational Commission on Foreign Medical Graduates, and the Pan American Health Organization; further, authorized the committee to seek outside funding, following established procedures and working in conjunction with the Medical Director's office, to support the development of this directory (Dec. 1991).

5. Approved printing on APA stationery a form to be used as an official APA document for investigating human rights abuses and abuse/misuse of psychiatry (Dec. 1991).

6. Approved printing the document "Human Rights and the APA" in booklet form for distribution to interested members and parties in other countries (March 1992).

7. Voted to request executives of the World Psychiatric Association (WPA) to advise the All Union Society of Psychologists and Narcologists of the U.S.S.R. that their conditional membership will be revoked if the criteria for readmission are not fully met; further, voted to strongly urge the WPA to provide the necessary funding to support the requisite site visit (June 1991).

8. Approved statements recommending that the WPA revoke the membership of the All Union Society of Psychiatry and Narcologists of the U.S.S.R. for failing to adequately fulfill the conditions placed on the restoration of membership by the WPA General Assembly in October 1989 and that the WPA (in the light of recent political developments in the Soviet Union) be prepared to expand its contacts with Soviet psychiatry by recognizing recently established and newly emerging psychiatric associations as they fulfill the standards and requirements of the WPA (Sept. 1991).

9. Authorized APA cosponsorship of a joint Soviet-American conference on ethical issues in psychiatry with the Georgetown-Johns Hopkins Program in Law, Ethics, and Health, the Program in Medical Ethics of the University of Wisconsin School of Medicine, and the Schell Center on International Human Rights; further, authorized the Council on International Affairs, following established procedures and working in conjunction with the Medical Director's office, to seek outside funding to cover the costs of the conference (June 1991).

Judicial Activities

1. Ratified an Executive Action taken by the President, the Speaker, and Dr. Carolyn Robinowitz, Acting Medical Director, authorizing APA to sign onto a brief prepared by the American College of Obstetricians and Gynecologists and filed in the Supreme Court case *Planned Parenthood of Southeastern Pennsylvania v. Robert P. Casey* (March 1992).

2. Ratified an Executive Action taken by the President, the Speaker, and Dr. Carolyn Robinowitz, Acting Medical Director, authorizing APA to sign onto a brief prepared by the National Alliance for the Mentally Ill and filed in the U.S. Court of Appeals for the Second Circuit in the case *Disabled American Veterans v. U.S. Department of Veterans Affairs* (also signing onto the brief were the Mental Health Law Project and the National Mental Health Association) (March 1992).

3. Authorized APA to file an amicus curiae brief with the U.S. Supreme Court in *Foucha v. Louisiana*, a case involving the question of whether defendants acquitted on the basis of the insanity defense may be kept hospitalized, once they are no longer mentally ill, solely on the grounds of dangerousness (May 1991).

4. Authorized APA to file an amicus curiae brief in the Second Circuit Court of Appeals in the case *U.S. v. Steven Diamond* (Sept. 1991).

5. Ratified the Executive Action taken by the President, Speaker, and Medical Director authorizing APA to file an amicus brief in the Supreme Court in support of the petitioner in *Riggins v. Nevada* (Dec. 1991).

Liaison Activities

1. Authorized APA to participate, at no cost to APA, in a joint APA and American Bar Association work group (under the aegis of the Council on Children, Adolescents, and Their Families) addressing the problems of children damaged by the divorce process and the adversarial system; further, authorized a liaison with the American Bar Association through the council for the narrow and express purpose of assisting with the proposed study (approximately 2 years) (Sept. 1991).

2. Approved APA cosponsorship of the Behavioral Healthcare Symposium to be held Sept. 9–12, 1992, in Chicago (Dec. 1991).

3. Authorized APA to develop guidelines for psychiatrists working in public and private organized systems of care; further, authorized APA to work with the National Association of Private Psychiatric Hospitals in its revision of guidelines (Dec. 1991).

4. Voted to send a clear message to the board of the National Association of Private Psychiatric Hospitals that APA does not support its admission standards and that APA questions its definition of a psychiatrist (Dec. 1991).

5. Approved a resolution to support the following guidelines for psychiatrists who admit patients to hospitals: a) every admission, voluntary or involuntary, must be clinically justified by the admitting psychiatrist; b) each patient admitted by a psychiatrist may be admitted only after he or she is evaluated face-to-face by the admitting psychiatrist who determines the necessity of the admission; and c) in an emergency, the admitting psychiatrist may order by telephone whatever measures are needed for the safety of the patient (the face-to-face evaluation should occur as soon as possible but no longer than 6 hours after an emergency admission) (this emergency provision excludes children under age 14, each of whom must be seen by a psychiatrist before admission) (March 1992).

6. Approved APA's becoming an organizational member of the Liaison With the National Coalition on Alcohol and Other Drug Issues, at no cost to APA (Dec. 1991).

7. Authorized APA to give high priority to efforts to have a psychiatrist appointed to the National Committee on Vital and Health Statistics (Dec. 1991).

8. Approved APA's participation with the National Foundation for Depressive Illness, Inc., to develop a program for educating generalists about affective disorders (Sept. 1991).

9. Approved APA cosponsorship of the 1992 National Mental Health Association Scientific Symposium, to be held Aug. 9–11, 1992, in Charleston, S.C. (March 1992).

10. Authorized continued liaison with the Rehabilitation Services Administration through the Council on Psychiatric Services and payment of travel expenses from the budget of the Council on Psychiatric Services (June 1991).

11. Authorized the President to select nominees that can be recommended to the Utilization Review Accreditation Committee board of directors to serve on committees that will be developing standards and accreditation procedures, with the understanding that APA would bear the travel costs of such representatives (June 1991).

Managed Care

1. Voted to return the \$26,535 given by the Connecticut Psychiatric Society to APA to support litigation in the managed care industry with a strong expression of APA's appreciation (plus the interest that accrued in the escrow account) (Dec. 1991).

2. Adopted the strategic groupings and priorities for addressing managed care issues as listed in the "Report of the Assembly Ad Hoc Task Force on Managed Care" and referred the report to the Committee on Managed Care, requesting that it report back to the Board, and thanked the Assembly for its major efforts and hard work (Dec. 1991).

3. Created the four-member joint Assembly and Board Task Force to Review Medical Necessity and Reimbursement Criteria for Use by Managed Care Organizations and Payers of Psychiatric Care, to provide consultation to the General Electric Corporation and to respond to subsequent requests from other organizations; further, allocated \$3,000 from the Board of Trustees contingency fund to support start-up costs of this component (June 1991).

4. Adopted guidelines to be considered whenever APA provides criteria review for the managed care industry (Dec. 1991).

5. Approved the policy that APA will not endorse externally developed utilization review criteria and voted that this policy should be made known to parties seeking endorsement or review and that no promise of review should be given when parties inquire about review; further, voted that the triage mechanism for incoming criteria be implemented (i.e., that an executive committee, consisting of the chairpersons of the Council on Economic Affairs and the Committee on Quality Assurance plus a deputy medical director, review the incoming criteria to decide APA's interest in pursuing them further) (Sept. 1991).

6. Authorized APA to develop guidelines for psychiatrists working in public and private organized systems of care (Dec. 1991).

7. Endorsed publication of "Utilization Management: A Handbook for Psychiatrists" as a task force report, contingent on a positive response from the Assembly Executive Committee (within 1 week or 10 days), noting that if a conflict emerges, the Executive Action mechanism will be used to decide whether to publish this document (Sept. 1991).

8. Ratified an Executive Action taken by the President, Speaker, and Medical Director to approve publication and wide distribution of "Utilization Management: A Handbook for Psychiatrists" (Dec. 1991).

Membership

1. Approved advancement of 179 General Members to Fellow status; approved advancement of three Life Members to Life Fellow status; and deferred advancement of 41 General Members to Fellow status (names on file) (Dec. 1991).

2. Approved 31 applications for Corresponding Membership; approved six nominations for new Corresponding Fellows; and approved the advancement of one Corresponding Member to Corresponding Fellow (names on file) (Dec. 1991).

3. Authorized holding a feasibility meeting in early 1992 to allow an in-depth exploration of membership directory issues by selected members of the Committee on Membership, the chairperson of the Committee on Biographical Directory and Research on Psychiatric Professional Activities, and APA staff (as assigned by the Senior Deputy Medical Director, Dr. Robinowitz) (Dec. 1991).

4. Authorized the Committee on Membership to produce a limited membership directory by 1994, creating a subcommittee on this project; further, authorized the Committee on Membership to develop a budget and to seek outside funding, following established procedures and working in conjunction with the Medical Director's office, to support this project (March 1992).

5. Approved dues relief and/or transfer to Inactive status for 323 members; denied dues relief and/or transfer to Inactive status for 32 members; and approved 37 requests for dues relief and/or transfer to Inactive status pending district branch recommendations (names on file) (Dec. 1991).

6. Encouraged members who were called to active duty for Operation Desert Shield and/or Desert Storm to apply for dues relief if needed; further, voted to request that such an announcement be published in an upcoming issue of *Psychiatric News* (June 1991).

7. Voted to expel Dr. Pradeep B. Kakkad from APA and the Illinois Psychiatric Society for noncompliance with conditions imposed on him as a suspended member (as a past chairperson of the Ethics Committee, Dr. McDevitt abstained from the vote) (June 1991).

8. Voted to expel Dr. Sergio Toscano from APA for violation of section 1, annotation 1, and section 2, annotation 2, of the *Principles of Medical Ethics With Annotations Especially Applicable to Psychiatry*; further, voted to request that the Ethics Committee approve reporting the expulsion of Dr. Toscano to the Mexican Psychiatric Association (Dec. 1991).

9. Approved the nominations of Jean Endicott, Ph.D., Patricia van Ameringen Kind, Ph.D., and Rachel Gittelman Klein, Ph.D., for Honorary Fellowship in APA; further, voted to elevate Leo E. Hollister, M.D., from Associate Member to Distinguished Fellow (Dec. 1991).

10. Authorized a market research study on membership services; approved funding from the 1992 budget (not to exceed \$20,000) for the portion of this study not funded by other entities; and authorized the work of the Ad Hoc Work Group to Advise the Membership Committee on Membership Losses to continue through the completion of this project and to include oversight of the marketing studies and coordination of input from the involved entities (Dec. 1991).

11. Endorsed actions taken by the Assembly regarding meeting the needs of military psychiatrists eligible for APA membership who are on active military duty (Dec. 1991).

12. Voted to change the "Operations Manual of the Board of Trustees" to include language that would permit the use of proof of acceptance to sit for examination by either the ABPN or the Royal College of Physicians and Surgeons of Canada as a method of demonstrating eligibility for APA General Membership for psychiatrists who received psychiatric training abroad, with the understanding that Dr. Aron Wolf, chairperson of the Committee on Membership, would consult with Dr. Munoz on the final wording (Dec. 1991).

13. Voted to deny an application for General Membership submitted by the Oklahoma Psychiatric Association because the applicant did not fulfill the requirement of completion of a psychiatry residency training program approved by the Accreditation Council for Graduate Medical Education (ACGME) (name on file) (June 1991).

14. Voted to deny applications for General Membership submitted by the Massachusetts Psychiatric Society and the Quebec and Eastern Canada District Branch (two applications apiece) because none of the applicants fulfilled the requirement of completion of an ACGME-approved psychiatry residency training program (names on file) (June 1991).

15. Denied membership to an applicant for Member-in-Training from the Iowa Psychiatric Society who is receiving psychiatric training from a residency training program approved by the American Osteopathic Association, unless he enters an ACGME-approved program (name on file) (Dec. 1991).

16. Deferred two applications from the Massachusetts Psychiatric Society, one from an applicant who does not meet the requirements for General Membership and one from an applicant who is attending a training program not approved by the ACGME and therefore does not meet the requirements for Member-in-Training status (names on file) (Dec. 1991).

17. Approved an application from the New Jersey Psychiatric Association for General Membership (name on file) (Dec. 1991).

18. Voted not to change the membership enrollment date of a Member-in-Training whose application through the Northern California Psychiatric Society took 18 months to process (name on file) (Dec. 1991).

19. Voted to drop from membership 562 members whose dues were in arrears for 1990 (names on file); further, recommended that administrative reinstatement be authorized for those who returned to good standing by Sept. 14, 1991, and were also in good standing in their district branches (June 1991).

20. Authorized dropping from APA membership as of Oct. 1, 1991, seven members who were in arrears for 1990 APA dues (names on file); further, authorized administrative reinstatement of those who returned to good standing in APA and were in good standing in their district branches by Nov. 1, 1991 (Sept. 1991).

21. Authorized dropping from APA membership 17 members who were in arrears for 1990 APA dues (names on file) (Dec. 1991).

22. Authorized dropping 118 Medical Student Members who had graduated from medical school unless they submitted appropriate documentation to enable them to advance to Member-in-Training status (names on file) (Dec. 1991).

23. Authorized dropping from APA membership as of March 1992

a member who failed to meet the membership requirement of completion of an ACGME-approved residency training program (name on file) (March 1992).

24. Voted to drop from APA membership 230 members who had been dropped by or had resigned from their district branches (names on file); further, authorized administrative reinstatement of those who returned to good standing in their district branches and were also in good standing in APA (June 1991, Sept. 1991, Dec. 1991, March 1992).

Minority Activities

1. Voted to release to the authors the monograph "Ethnic Differences: Do You Amend Your Therapeutic Approach?" for independent publication, provided that references to APA were removed (Dec. 1991).

2. Approved the position statement on homosexuality and the U.S. Immigration and Naturalization Service (4) (June 1991).

3. Authorized the Committee on International Medical Graduates, following established procedures and working in conjunction with the Medical Director's office, to seek outside funding (approximately \$8,000) to produce and distribute a newsletter for international medical graduates (three issues per year with a circulation of 8,000) (June 1991).

4. Authorized the Committee on International Medical Graduates to seek approximately \$6,000 in outside funding, following established procedures and working in conjunction with the Medical Director's office, to support publication of proceedings of the last two international medical graduate regional meetings, with the understanding that the publications would not carry the imprimatur of APA (Dec. 1991).

National Issues

1. Approved the position statement on reproductive rights (5), contingent on the approval of the Assembly (which approved it in November 1991) (Sept. 1991).

2. Voted to release to the authors the series of papers concerning nuclear issues and military economy that were presented during the symposium "Psychosocial Dynamics of Big Defense Spending," sponsored by the Committee on Psychological Aspects of Nuclear Issues, at the 1990 annual meeting, with the understanding that APA's name would not be associated with the documents (June 1991).

3. Approved the following position statement on the right to privacy: "Be it resolved that the American Psychiatric Association supports the right to privacy in matters such as birth control, reproductive choice, and adult consensual sexual relations conducted in private, and supports legislative, judicial and regulatory efforts to protect and guarantee this right" (Dec. 1991).

4. Authorized the Committee on Telemedical Services, following established procedures and working in conjunction with the Medical Director's office, to seek outside funding (up to \$5,000) to support an exhibit and workshop to be held during the 1992 annual meeting (Sept. 1991).

5. Approved Area VI Action Paper 1, "Nondiscriminatory Coverage of Potentially Disabling or Life Threatening Mental Disorders," as approved by the Assembly in November 1991, assigning the responsibilities for the study to the Committee on Universal Access to Health Care, with authorization for two additional members of the committee and additional funding as approved in the 1992 budget (Dec. 1991).

Public Psychiatry

1. Authorized the Council on Psychiatric Services to invite the chairpersons of the Committee on Veterans' Affairs, the Committee on Psychiatric Services in Jails and Prisons, the Committee on Psychiatric Services in the Military, and the Committee on Psychiatric Services for Mentally Retarded and Developmentally Disabled Persons and a representative from the Assembly Committee of Representatives of Minority/Underrepresented Groups to join the consortium; further, authorized the Council on Psychiatric Services to review requests for representation and, subsequently, to directly invite

groups to join the consortium as the council sees appropriate (Dec. 1991).

2. Voted to request that the *Psychiatric News* Editorial Board consider a request from the Assembly Committee on Community Psychiatry to incorporate information from the public psychiatry network newsletter as a regular feature in *Psychiatric News* (Dec. 1991).

3. Approved the following recommendations regarding services in public mental health programs: a) a consideration in the review of a nominee for Fellowship in APA shall be work experience or contribution of time in a public mental health program; b) psychiatrists should be encouraged to work in or volunteer some time in public mental health programs; c) in the next biographical survey the amount of time each psychiatrist works in or volunteers in a public mental health program should be clearly quantified; d) APA and district branches should develop mechanisms to recognize those who provide or volunteer for direct services to the severely mentally ill; e) APA should encourage public mental health programs to develop ways in which psychiatrists may volunteer or provide services, teaching, supervision, or advocacy (June 1991).

4. Authorized the next biographical survey (or the next appropriate sample survey) to include clear categories to capture and differentiate the amount of time psychiatrists spend in various public psychiatric services (e.g., uncompensated care, care for the severely mentally ill, volunteer or paid services in public psychiatry agencies) (Dec. 1991).

5. Approved the following statement regarding rehabilitation services: "Psychiatric diagnosis and treatment should be promoted as an essential component of any rehabilitation program for severely mentally ill persons" (June 1991).

6. Approved the following statement regarding nondiscriminatory coverage for severely mentally ill persons: "Severely mentally ill persons should have access to and reimbursement for care equal to that of other psychiatric and medical patients" (June 1991).

7. Authorized APA to negotiate with pharmaceutical companies to sponsor opportunities for public psychiatrists to broaden their knowledge base, upgrade their technology, and achieve some respite from their demanding jobs through a recognition program (e.g., a fellowship in an academic center, a traveling or visiting scholar award, a research sabbatical, or an exchange of an academic psychiatrist with a public psychiatrist) (Dec. 1991).

8. Adopted the model job description for medical/clinical director in state mental health authorities (Dec. 1991).

Research

1. Approved establishing a subcomponent of the Committee on Research on Psychiatric Treatments, within the Council on Research, to develop a report on antidepressants and suicide, using existing council and committee funds (Sept. 1991).

2. Approved several resolutions to assist district branches in their efforts to refute attacks against ECT (June 1991).

3. Authorized APA to accept a professional services contract (approximately \$25,000) from the ADAMHA Office for Science for analysis of APA Faculty Survey data (Sept. 1991).

4. Authorized APA to accept funding (approximately \$7,000) from NIMH to pay for the printing of extra copies of *Psychiatric Research Report* for Members-in-Training (Sept. 1991).

5. Authorized APA to accept a professional services contract (approximately \$25,000) from NIMH for analysis of APA Professional Activities Survey data (Sept. 1991).

6. Authorized APA to accept a professional services contract (approximately \$25,000) from the National Institute on Drug Abuse for analysis of APA Professional Activities Survey data (Sept. 1991).

7. Authorized APA to accept professional services contracts (approximately \$25,000 each) from NIMH for data analysis related to research training (Sept. 1991).

Subspecialization

1. Approved APA's endorsement of added qualifications in forensic psychiatry and voted to notify the ABPN of APA's endorsement (June 1991).

Youth

1. Approved the document "Disclosure of Psychiatric Treatment Records in Child Custody Disputes" for publication as a report from the Task Force on Disclosure of Psychiatric Records in Child Custody Disputes, incorporating word changes prepared by Drs. Wiener and Zonana (June 1991).

2. Approved the "Position Statement on Day Care for Preschool Children" (6) and extended the tenure of the Task Force on Day Care for Early Pre-School Children until December 1993, to permit monitoring of day care legislation (Dec. 1991).

Report of the Treasurer

Mary Jane England, M.D.

EXECUTIVE SUMMARY

Economic pressures on APA fiscal operations

U.S. economy continues in recession.

APA business cycle hits low point.

Results of 1991 financial operations

Revenue of \$24,263,081 received.

Expenses held to \$24,136,307.

Membership

Membership increased by net of 361 members during 1991—to total of 37,279 members.

Dues tied to inflation—resulting in 4.4% increase for 1992.

Lump-sum dues option chosen by 60 members.

Ballot initiative passed, approving reduced dues for Life Members/Fellows (elected effective 1993).

Member-in-Training dues restructured.

Debt management

APA borrowing for cash flow held to \$2.8 million.

APA obtains loans with favorable terms ($\frac{1}{2}\%$ over prime rate).

Association maintains record of repaying all loans in full and on time.

Strategic financial planning

Board of Trustees established Financial Planning Subcommittee of the Budget Committee in March 1991.

Goal of \$1.8 million (3 months' payroll) set for liquid reserve to reduce reliance on borrowing.

APA auditors reported sound financial statements, accounting system, and budget process.

Plans set in place to smooth out APA business cycle.

Procedure for review of total employee compensation (salaries and fringe benefits) implemented.

Vehicle for oversight of investments refined.

Operations streamlined through reorganization and automation.

Capital budget implemented.

Potential programs identified to increase nondues revenue.

Budget Committee acts as catalyst in development and prioritization of APA mission and goals.

the amount that APA will need to draw on its line of credit. This is a small step toward the high-priority financial goal of debt reduction through the establishment of liquid reserves.

In March 1992 representatives of APA's independent accounting firm, McGladrey & Pullen, presented a detailed report to the Board of Trustees on the results of their audit of APA's 1991 financial operations.

SERVICES FOR MEMBERS

Just as APA's most important resource is its members, its most important function is service to members and their patients. As of Jan. 1, 1992, total APA membership stood at 37,279. The Association realized a net gain of 361 members during 1991, which contrasts sharply with an average net gain of over 1,000 members per year during the 1980s. This plateauing of membership growth is projected to continue for the foreseeable future, primarily because the number of new members is expected to remain relatively stable.

Another membership trend is pertinent to this Treasurer's report; i.e., while the number of dues-paying members increased by 0.25% during 1991, the number of non-dues-paying members increased by over 5%. These figures for 1991 are actually part of a trend over the past several years showing a decrease of dues-paying members compared to an increase of non-dues-paying members.

The Association is making progress in offsetting the fiscal effects of this trend. First, 60 members have selected the recently available option of paying APA dues in a lump sum. This program has led to receipts totaling approximately \$400,000 to date. Second, approval was given to a constitutional amendment included in the 1992 ballot that permits charging newly elected Life Members/Fellows (elected effective 1993 and beyond) reduced dues rates for 10 years after conversion to Life status, whereas Life Members/Fellows have paid no dues in the past. Third, beginning in July 1991, a \$40 communications fee was approved for Life Members/Fellows who wish subscriptions to the *American Journal of Psychiatry*, formerly a perquisite of membership. Life Members/Fellows who will now pay limited dues will continue to receive the *American Journal of Psychiatry* at no charge.

At the same time, the Association has taken steps in response to the financial implications of another trend within its membership, namely, the growing population of Members-in-Training. APA has instituted a seven-step dues structure to reduce the dues burden of members who have recently completed residency and have just begun practice.

The Association strives to keep in step with the needs of its members. APA growth during the 1980s represented a response to growing member needs during that period. As plans were developed for fiscal year 1991, the leadership heard a clear message from members regarding their changing financial picture. The Association's response was also clear. Growth has been replaced by a hold-the-line budget. Dues increases beyond inflation, which helped to support the 10-year growth, have been replaced by dues rates tied to the rate of inflation. The dues increase for 1992 was 4.4%.

As an APA member you need to know that the Association focuses heavily on your needs, your problems, and your priorities. Only through your professional association can many of the needs that you face be addressed—and only through your communication of those needs can your views help shape APA's priorities.

RESPONSE TO ECONOMIC PRESSURES

In 1991 American corporations continued to post reductions in the scope of operations, level of output, and profits—while individual

GENERAL

This report is prepared from audited figures for the fiscal year that ended Dec. 31, 1991. The data presented also appear in the auditor's annual report.

Table 1 is a statement of our financial condition, taken from the independent auditor's report, and table 2 reflects functional revenues and costs. These will provide the membership with information needed to assess the operations and financial condition of the Association.

SUMMARY OF FISCAL RESULTS OF 1991 OPERATIONS

APA implemented a break-even budget for 1991 despite substantial obstacles posed by the national economy. Actual revenues of \$24,263,081 were below budget estimates by \$134,522, or about 0.5%. A shortfall in revenue had been anticipated early in the year, which prompted efforts to bolster revenue and curb costs. The resulting savings led to actual expenditures for the year that were approximately 1% below budget authorizations, i.e., the actual expenses of \$24,136,307 were below budget by \$261,296. As a result of the measures to ease pressures on the budget, APA realized a surplus from operations in 1991 of \$126,774, which amounts to roughly 0.5% of the budget.

The practical benefit of this modest surplus is that it will help reduce

TABLE 1. APA Balance Sheets as of Dec. 31, 1991 and 1990

Item	Amount (dollars)	
	1991	1990
Assets		
Current assets		
Cash and cash equivalents	2,365,187	1,451,734
Marketable securities	—	652,561
Accounts receivable, less allowance for doubtful accounts	1,491,874	1,387,536
Grants and contracts, approved and in process	2,207,835	2,172,286
Advances to affiliates	1,607,283	1,128,239
Publications inventory	493,486	495,093
Prepaid expenses and other current assets	397,635	396,004
Total current assets	8,563,300	7,683,453
Property and equipment		
Land	5,187,470	5,187,470
Building—leasehold interest and improvements	7,073,142	7,104,926
Furniture and equipment	2,595,327	2,446,675
Subtotal	14,855,939	14,739,071
Less accumulated depreciation and amortization	3,321,215	2,804,993
Total property and equipment	11,534,724	11,934,078
Other assets		
Deferred expenses, net of accumulated amortization	3,294,313	2,615,926
Deferred land rent	770,337	809,578
Intangible pension asset	—	231,307
Total other assets	4,064,650	3,656,811
Total assets	24,162,674	23,274,342
Liabilities and fund balances		
Current liabilities		
Accounts payable	617,141	1,381,929
Accrued expenses	2,257,222	1,865,145
Deferred revenue	1,765,281	1,344,300
Deferred amounts		
Restricted—grants and contracts	2,017,054	1,508,808
Restricted—awards and special projects	2,616,820	2,165,160
Total current liabilities	9,273,518	8,265,342
Other liabilities		
Capital lease obligation, less current maturities	4,414,996	4,430,070
Accrued pension cost	—	231,307
Total other liabilities	4,414,996	4,661,377
Fund balances		
Unappropriated	6,204,816	6,078,042
Appropriated	150,000	150,000
Building	4,119,344	4,119,581
Total fund balances	10,474,160	10,347,623
Total liabilities and fund balances	24,162,674	23,274,342

Americans contended with losses in their confidence in the economy, their financial security, and their jobs. The economy stalled again last year, in part because of a continuation of recessionary pressures. The economy was further weakened by a restructuring of many corporations (General Motors was a prime example) that were striving to trim costs and enhance efficiency. As a practical matter, the entire process was termed "the recession" by the media and most of the citizenry, and the results were as negative as the label.

At this point I should briefly mention something that has been discussed in detail in earlier Treasurer's reports, namely, that APA currently operates on a business cycle, just as many organizations do. This means that the Association has some financially strong years, then some weak years, then the cycle continues. Although a mechanism has been put in place to smooth out the business cycle in the future, it was in full effect in 1991. The point is that the recession hit

TABLE 2. APA's Functional Revenues and Costs for Fiscal Years 1991 and 1990

Item	1991	1990
Functional revenues		
Percent from each function		
Publications		
Advertising	16.50	18.84
Subscriptions and related fees	8.22	6.72
Book sales	15.78	16.65
Member services		
Dues from members	39.02	36.40
Meetings income	13.22	12.78
Other income related to member services	2.38	2.37
Other income (investments, overhead on grants, contributions, etc.)	4.88	6.24
Total revenues (dollars)	24,263,081	24,907,182
Functional costs		
Percent for each function		
Governance and member component activities (Board of Trustees, Assembly, joint commissions, councils, and components)	16.26	15.50
Publications (APA journals and book sales)	29.77	29.76
Public affairs (public information and government relations)	10.15	10.33
Member services (membership services and educational programs)	26.12	27.16
General administrative costs	17.70	17.25
Total costs (dollars)	24,136,307	24,257,444

at exactly the same time as APA hit a low point in its own business cycle.

Although the federal government reports that the recession started in August 1990, economic data show that the economy was actually in decline in the spring of 1990. Although some APA revenue-producing programs experienced a revenue downturn early in 1991, these shortfalls were offset by strong revenue production by other programs for the first 9 months of the year. As a result, APA's overall financial operations did not show the symptoms of recession until October 1991. In other words, the recessionary pressures that were causing serious problems for many companies in the spring of 1990 did not have a heavy impact on APA until 1½ years later. While this was good fortune for the Association, our good fortune was enhanced by our own efforts to stimulate revenue, cut costs, and maintain strong ties with a weakened banking community.

APA revenue fell short of estimates for 1991 since recessionary pressures on the Association were pronounced during the last 4 months of the year. Nevertheless, revenues were maintained close to budget estimates because of very positive book sales, annual meeting receipts, and subscription sales for the *American Journal of Psychiatry*. In addition, financial support from grants and contracts from the federal government and private foundations enabled the Association to provide a number of needed products and services without placing an additional burden on our fiscal resources.

Although the impact of the recession on APA was not significant until late in 1991, this problem had been predicted many months in advance. The projected revenue shortfall was communicated to component chairpersons and department heads early in the year, and they were urged to stimulate revenues and carefully monitor expenditures. It was only through the diligence of our member and staff leaders in working to bolster revenue and to keep costs in line with budget estimates that a break-even budget was achieved. Certainly, the financial crunch was felt throughout the organization as a freeze was placed on filling new positions, equipment purchases, and travel. But the result was worth it. Expenses were not only enough below budget to

offset the revenue shortfall but were enough to generate a surplus from 1991 operations as well.

DEBT MANAGEMENT

As a result of effective cash management, borrowing on the Association's seasonal line of credit in 1991 was held to \$2 million. At year end, all drawings on the line of credit had been repaid in full. Projections indicate that borrowing will increase during the remainder of 1992 and throughout 1993, reaching a high point of \$6.5 million in 1993.

APA has continued to maintain a solid relationship with local banks despite a continuing deterioration of the financial position of banks in general and a growing reluctance of banks to provide favorable terms or even to make loans. In fact, one of the primary reasons cited for the heightened level of corporate bankruptcies in recent years has been the inability of many corporations to obtain renewals of bank loans.

During this period of a weakening banking community, APA has not only obtained bank loans as needed but has obtained loans with favorable terms. Highlights of the Association's current loan package are as follows.

Term loan—maximum limit of \$1,500,000 at ½% over the prime rate. As of Dec. 31, 1991, there were no borrowings through this mechanism. Any future borrowings are due and payable by Oct. 1, 1993.

Line of credit—maximum limit of \$5,000,000 at ½% over the prime rate. The stability of the cash budget was evidenced by the fact that the line of credit was used during only 4 months of 1991 and only \$2,750,000 of the line needed to be used.

The hallmarks of APA's debt management in the past have been to maintain ongoing liaison with selected local banks, to maintain a sound financial position, and to honor all commitments to banks, including the repayment of all loans fully and on time—with no exceptions. Although this debt management posture has stood APA in good stead, the Association is moving to a higher level of debt management. We are assuming a more aggressive and proactive stance with respect to borrowing by reducing the amount of borrowing in the first place. APA is moving to a position of self-sufficiency.

NET WORTH

The Association's stated net worth (reserves) has increased from approximately \$4 million in the mid-1970s to roughly \$10.5 million today (\$10,474,160). This stated figure is extremely conservative, since it does not include the estimated appreciation in value of the 1400 K Street property purchased by APA in 1980. The increase in net worth is particularly impressive in recent years, even after the impact of inflation is considered, from \$7,486,501 in 1984 to \$10,474,160 as of Dec. 31, 1991. As noted elsewhere in this report, the Association is planning not only for continued growth of its net worth but for an enhancement of liquid (cash) net worth.

STRATEGIC FINANCIAL PLANNING

The Budget Committee, through its Financial Planning Subcommittee, has moved ahead in its efforts to set a strategic fiscal agenda for the Association. The subcommittee has met twice since its establishment by the Board of Trustees in March 1991. Working on a 3–5-year planning time frame, the subcommittee had established a series of APA fiscal goals by August 1991 and, in addition, had assigned staff specific tasks relative to the implementation of those goals. Following are highlights of progress in the establishment and achievement of these fiscal goals.

Reduction of Borrowing Through Development of Liquid Reserves

APA's target for liquid reserves is an amount equal to 3 months of staff salaries, i.e., \$1.8 million. As mentioned earlier, the Association's surplus from 1991 operations of \$126,774 is an initial step

toward this goal. The 1992 budget contains provisions for a cash operating surplus of \$300,000 to add to liquid reserves. The strategic financial plan calls for an aggregate cash operating surplus amounting to \$1.5 million for the 4-year period 1993 through 1996 to achieve this target.

Smoothing Out of Business Cycle

The peaks in the APA business cycle are the result of strong revenue, and the troughs in the cycle stem from weak revenue. Plans are currently in place to begin smoothing out the Association's business cycle at the time of its next peak, which is expected in 1994. This will be accomplished by shifting revenue from stronger to weaker years.

Review of Total Employee Compensation, Including Salaries and Fringe Benefits

Future reviews and deliberations regarding staff salaries and fringe benefits are to be conducted within the context of total compensation. APA's staff and consultants began working on this assignment during the last quarter of 1991. Using a nationwide survey by another medical specialty, APA has compared the salaries and benefits of its higher-salaried staff with those of other medical specialty associations. It was found that the salaries and fringe benefits provided by APA are well within the ranges of those of other medical specialty associations having annual budgets of \$20 million and more. APA is participating in several local salary surveys and will use the results of these surveys in the review of total compensation of lower-salaried staff. However, these efforts are only a beginning. As the Association attacks the problems of ongoing salary reviews, the costs of staff benefits, and many other related matters, these complex issues will be considered within the context of total employee compensation, using our rapidly growing data base in this area.

Exploration of Options for Managing Investments and Improving Their Performance

In the mid-1970s approximately 60% of the Association's asset base was contained within its investment portfolio. For this reason, APA established the Investment Advisory Committee, comprising well-known and successful financiers from the Washington, D.C., area.

The investment portfolio has now been reduced in size to only 3% of the Association's asset base because the majority of APA's investments relate to the 1400 K Street building program. Oversight of the portfolio now rests with the Asset Management Advisory Committee, composed of two members of the APA fiscal staff and two consultants in the areas of finance and benefits, respectively. The assets of the portfolio are currently folded into the larger portfolio of the Washington, D.C., financial institution ASB Capital Management to achieve the benefits of greater diversification of investments.

Streamlining of Operations Through Reorganization and Automation

The Association has achieved budget savings and operating efficiencies through departmental reorganization, computerization of numerous activities (including budgeting and financial forecasting), and other technical enhancements, such as desktop publishing. Similar proposals are currently being developed, and component chairpersons and department heads will be encouraged to contribute ideas as they develop their 1993 budget proposals.

Implementation of Capital Budget

The 1993 budget package will include not only the traditional annual operating budget but also a capital budget. The capital budget will focus on requests for new facilities, such as additional or improved office space; equipment purchases (computer or communications hardware, for example); multiyear research or program development projects, such as DSM-IV or the *Biographical Directory*; grants from governments or foundations, provided full overhead is

allowed by the grantor; and gifts from corporations or individuals to support specified APA programs, provided matching is not required from the APA general fund.

Identification of Means of Strengthening Balance Sheet and Profit-and-Loss Statement Without Increasing Member Dues

The Financial Planning Subcommittee has identified a number of potential programs for producing nondues revenue. The feasibility of implementing the potential programs is being explored, and this exploration includes market research and discussions with other associations and consultants. Efforts to curb costs have been discussed throughout this report. Some of the most effective cost-control efforts

include freezing various expense categories and systematically monitoring budget implementation.

Development and Prioritization of Mission and Goals

It is envisioned that the Budget Committee will serve as a catalyst for APA leadership to develop a crisp statement of APA's missions and goals. The next step is one that has proven to be difficult in the past, i.e., the prioritization of the mission and goals. As challenges to the field of psychiatry mount, and as the financial resources to meet those challenges fade, prioritization becomes essential. Although this goal is stated last on this list, it could well prove to be the key to all other goals and, thus, the most important goal of all.

Report of the Medical Director

Melvin Sabshin, M.D.

During my tenure as APA Medical Director, this report has become a useful reflection of progress and problems. We have indeed been coping with remarkable challenges; the themes of socioeconomic and political ferment have dominated my reports for some time. The coping process has been accompanied by an increased diversity and complexity of the functions assumed by the national leadership and the Central Office. Since last year's report, we have faced many difficult decisions and actions. There has been a leveling off in our membership, accompanied by a drop in the number of medical students choosing residencies in psychiatry. Psychiatry has been in the limelight in the media primarily in relation to ethical breaches, and there has been an increase in reporting and awareness of sexual interactions with patients. The "Frontline" television program attacked not only the profession but also the Association for its alleged role in a complex malpractice situation related to ethical issues. At the same time, we have had numerous successes, and I am pleased with the mood, strength, stability, productivity, and responsiveness of the organization. Both the tone and content of our activities are positive overall and demonstrate strong, effective working relationships between staff and members. Dr. Hartmann's thoughtful, dynamic, and effective leadership is reflected in the strength and enhancement of many departments' efforts.

APA staff has shown remarkable efficiency and productivity. While the quantity of work continues to increase, we have been able to maintain high quality, even in the face of increasing demands in many arenas. This year the Association has focused on how to provide the most cost-effective support and leadership for the diverse needs of more than 37,000 members while avoiding possible fragmentation resulting from increased interest in subspecialization and a variety of forms of practice. We have devoted much energy to consideration of the impact of managed care on APA members and their patients. Through extensive resources devoted to scientific activities, we are developing practice guidelines, as well as continuing to develop a reliable and valid diagnostic nomenclature. Our strength in public policy deliberations and in the decrease of stigma associated with care for mental disorders has depended heavily on our scientific growth and credibility as a field. We also have carefully monitored the Association's business-related work and fiscal affairs, as well as the more traditional specialty society membership efforts. To that end, we have queried our members through focus groups, paid careful attention to their written and oral comments, and have held frequent discussions with our counterparts in other medical specialties and mental health disciplines.

Currently, there are three search processes for senior positions in

various stages of completion. The search advisory committee charged to assist us in identifying a Director of the Office of Education, with members Drs. Jerald Kay, Paula Panzer, James Shore, and Joel Yager, has completed initial interviews of nearly a dozen psychiatrists. We are pleased at the interest shown by these candidates, who have broad experience in psychiatric education and administration. Some members continue to express concern that we have accepted outside funds for the position. We understand the considerations expressed and wish to avoid even the appearance of any control by an outside organization or industry. The funding has been given to APA without any encumbrances; Abbott Laboratories has had no involvement in any aspect of the search process, nor will it influence any aspect of the operation of the Office of Education. We do not see this important position as solely funded by an outside firm; rather, this donation enables us, particularly in these tight fiscal times, to recruit a psychiatrist director who will bring considerable experience and involvement to the position. We had delayed filling the position because of fiscal constraints. Ms. Rosalind Keitt, Interim Director, has been an extraordinarily effective leader who has worked well with the Council on Medical Education and Career Development and related educational organizations. She and Office of Education staff, as well as Drs. Spurlock and Robinowitz, are to be commended for their prodigious efforts in strengthening our educational productivity and performance. At the same time, members of the educational community have voiced their concerns that we fill the position as soon as possible, noting the importance of the position to psychiatry. (Since this report was written Dr. Jay Scully was named Director of the Office of Education.)

Dr. Jeanne Spurlock retired on Dec. 31, 1991, after nearly two decades of extremely devoted and effective service to APA. Dr. Spurlock has been an extremely articulate advocate for underrepresented groups—and her efforts did much to promote the quality of care delivered to minority populations, expand opportunities for minorities within the Association, and increase our awareness and understanding of issues affecting minority populations. The search for her successor also is under way. Ms. Hart, working with Dr. Robinowitz, will provide staff support to the search committee, which is chaired by Dr. Robert Phillips and has as members Drs. Donna Norris, Pedro Ruiz, and Dale Walker. A position description has been circulated, and we have already received excellent suggestions from the field.

I appreciate the remarkable efforts of Ms. Linda Roll, who, as Interim Director of the Office of Minority/National Affairs, is providing excellent staff assistance to our councils and components and supporting many activities in this area. I also appreciate the substantive

consultation provided by Drs. Spurlock and Henry Work to the Office of Minority/National Affairs in this interim period.

In November 1991 Dr. John Nemiah announced his intention to retire from his position as Editor of the *American Journal of Psychiatry*. Under his superb stewardship, the *Journal* has grown in scientific stature, while maintaining its literary excellence and readability. Dr. Nemiah has brought in the best of modern technology, while enriching the scholarly nature of our publication. He has led with wit, warmth, and grace. His working relationship with Deputy Editor Dr. Nancy Andreasen, Managing Editor Ms. Sandra Patterson, and staff has been exemplary. Dr. Hartmann has appointed a search committee charged to recommend his successor; this committee is chaired by Dr. Herbert Pardes, with members Drs. Glen Gabbard, Judith Rapoport, George Vaillant, and Joel Yager. Receiving staff support from Dr. Robinowitz, they too have requested suggestions of possible candidates from the field and have met with Dr. Nemiah and staff to develop criteria for the position. From the initial list of some two dozen candidates, they have identified 10 candidates for further consideration.

In September 1991 Dr. Marta De Titta, Director of the Office of Membership, resigned to return to her native Argentina. In her tenure at APA, Dr. De Titta brought a combination of energy, understanding, and concern to the work of the Office of Membership, maintaining interest in analysis of membership data and trends, while paying personal attention to each individual member's communication with the Association. I appointed Ms. Elizabeth Thomas, former Assistant Director, to serve as her successor. In addition to her excellent performance as Assistant Director, Ms. Thomas served quite effectively as the "ombudsperson" for our member insurance program. These changes sparked a number of staff position shifts. The Recruitment Coordinator, Ms. Dara Schumaier, was promoted to Special Assistant to the Senior Deputy Medical Director, where she serves half time as the "ombudsperson." Mr. Michael Murphy was promoted to Assistant Director of the Office of Membership, replacing Ms. Thomas.

It is with mixed feelings that I report the promotion of Mr. Murphy, formerly Administrative Assistant to the Assembly. I am pleased and proud of his promotion, which reflects the excellence he brought to his position as Administrative Assistant to the Assembly. Many of you have shared with me your appreciation of his effectiveness, organization, and attention to quality and detail. He brings these excellent skills to the Office of Membership. Additionally, Mr. Murphy has agreed to take on a further task. Ms. Corky Hart has provided staff support for the Joint Reference Committee for more than a decade, bringing her excellence in organization and her knowledge of APA and our components to the task. She has performed admirably and effectively. Over the past 6 months, however, her expanding duties in the Office of Psychiatric Services have infringed on the time available to maintain her high level of involvement with the Joint Reference Committee. Mr. Murphy will take over these efforts in addition to his work in the Office of Membership. He and Ms. Hart will work together to ensure a smooth transition and to work effectively with the next President-Elect and Speaker-Elect. We very much appreciate his willingness, in these tight fiscal times, to take on this added task, and we know that his experience in the Office to Coordinate the Board and Assembly will be advantageous in fulfilling this responsibility.

In October 1991, after 10 years of service to APA, Mr. Charles North retired as director of the Human Resources (formerly Personnel) Department. Mr. North contributed greatly to the development of standards and procedures as we moved from the informality of a small operation to a large professional organization that must address requirements and regulations, as well as problems of both management and support staff. I appointed Ms. Margaret Zieg, Assistant Director, to succeed him, and Ms. Debrah Brown was promoted to Assistant Director. I am most gratified with Ms. Zieg's quiet professionalism as she assists us not only in recruitment, evaluation, education, and retention of staff but also in dealing with benefits and morale enhancement during tight fiscal times.

Among the saddest news this year was the loss of past President Dr. George Tarjan. Dr. Tarjan had been an active contributor to so many activities—serving as a resource for staff and members alike. His constant availability and his cool-headed no-nonsense approach to problems were especially valued. He chaired the *Psychiatric News* Editorial Advisory Board, which reviews both policies and content of

the newspaper. Consultants from other publications (e.g., *AM News*) also provided valuable input. Under the leadership of Dr. Robert Campbell, Editor-in-Chief, and Mr. Herbert Gant, Executive Editor, *Psychiatric News* is demonstrating increased emphasis on meeting members' informational needs. A new section, highlighting psychiatrists' accomplishments and interests, is planned, as is a section containing debates; we also anticipate greater editorial focus.

We also were sad to learn of the death of past President Dr. John Spiegel. He too was a valuable resource to all of us, and his leadership in addressing social problems associated with mental disorders and his efforts to democratize APA's work were pivotal.

No report could be complete without some discussion of the long-term impact of the "Frontline" program. We continue to receive correspondence from members and others concerned with the statements made on the program. We had been unsuccessful in our interaction with the producers to try to correct the inaccuracies and misrepresentations in the program, nor did we persuade them to provide information to viewers about available resources. We appreciate your individual efforts to correct the misinformation. All in all, there have been two dozen phone calls and about 60 letters—mostly from members expressing feelings ranging from outrage at what they (incorrectly) perceived as APA policy regarding undue familiarity, to questions about why APA could not control the defense attorneys for Dr. Richter, to concern that APA had not intervened effectively in advance of the program to prevent its showing. All shared our distress at the impact of the case on Dr. Gay and her patient. I have personally answered each member, as have others in the leadership, and these efforts (in addition to the material included in *Psychiatric News*) made an impact. At the same time, this issue has caused major distress to members who did not choose to contact us. At district branch meetings, interactions with residents, meetings of other groups, and so forth, the topic continues to receive prime attention. The recent publicity over the practices of Dr. Margaret Bean-Bayog also reflects poorly on the field and has a negative impact on access to treatment and how treatment is conducted. While we have much in our ethical activities of which to be very proud, and we have developed strong preventive education programs and implemented responses to violations, much more needs to be done to address public perceptions and misperceptions.

The Division of Public Affairs has revised the "Fact Sheet on Doctor/Patient Sex." The content restates appropriate material from our code of ethics; describes how to file an ethical complaint; provides names and addresses of district branches, other professional organizations, and self-help groups; and includes an extensive bibliography. Copies are available from the division.

APA also issued a press statement on sexual harassment in response to discussions at the Senate hearings to confirm Clarence Thomas as Supreme Court Justice. The statement described the impact of sexual harassment and concluded, "Sexual harassment is destructive behavior that can cause profound psychiatric problems for its victims. It must not be tolerated in any setting."

Other ethical issues continue to be addressed. The misuse and abuse of hospitalization continues to receive publicity that unfortunately affects the entire field, causing even needed hospital admissions to be viewed with suspicion. Not only must we vigorously speak out against such abuse and the systems that engage in it but we also need to develop and publicize clear, scientifically based, reliable criteria for hospitalization.

In response to extensive media reporting of allegations of major problems with psychiatric hospitalization practices in several states and the numerous repeated expressions of concern by key Congressional staff about these allegations, I sent a letter to all members of the U.S. House of Representatives and Senate detailing APA ethical guidelines for hospital admissions. The letter also outlined actions that APA had requested its district branches to undertake. These included dissemination to the local community of information about how to file a complaint of ethical misconduct against a psychiatrist, review of current state psychiatric hospitalization laws, and, where necessary, work with state legislatures to improve those laws.

Similarly, the Dahmer trial had the potential to reinstate controversy about the "insanity defense" and, with it, to attack our diagnostic credibility and reliability. Although similar courtroom controversies exist in other medical specialties, they do not seem to have had

the same negative impact on the public (and other physicians), resulting in a slur on psychiatry—especially our diagnostic and treatment capacities. I was pleased with the quality of coverage and the understanding demonstrated by the media.

Our public affairs efforts must be strong, not only in responding to problems and issues but also in developing proactive strategies for dissemination of positive information and image enhancement. We have had much success in efforts such as Mental Illness Awareness Week, and our film on depression has reached many effectively, but we also must anticipate and, whenever possible, avert problems and use what Dr. Paul Fink has called a “psychiatric SWAT team” to respond to “hot” issues rapidly and effectively.

Dr. Allan Tasman has been a thoughtful and energetic chairperson of the Scientific Program Committee. This year he completes his tenure in that role. Under his direction, the program at the annual meeting has continued to expand in content and sophistication. There has been greater attention to integrating research findings into the scientific educational program and increasing emphasis on more interactive and participatory sessions for clinicians. The annual meeting is a high point of the year, an active and integrating force that mirrors directions for the field.

The planning of the program for this year, under the direction of Dr. Tasman and Dr. Michelle Riba, vice-chairperson, has been stimulating and fulfilling. The broad array of scientific presentations in a variety of formats offers excellent education for all participants. The President's theme has sparked a number of thoughtful and innovative symposia and workshops. The number of courses available has expanded in response to members' requests. Advance registration figures suggest another very well-attended meeting.

Dr. Jeffrey Akman, chairperson of the Local Arrangements Committee, and the committee members have been remarkably effective in identifying a host of leisure-time activities, taking advantage of the museums, institutions, and natural surroundings of Washington, D.C. Dr. English has appointed Dr. John Oldham as chairperson of the Scientific Program Committee for the 1993 meeting, to be held in San Francisco, May 22–27; Dr. Riba continues as vice-chairperson. Dr. English's Presidential theme is “Patient Care for the 21st Century: Asserting Professional Values Within Economic Constraints.” The leadership of the Scientific Program Committee met in March in San Francisco with local leaders and the Local Arrangements Committee, chaired by Dr. Lawrence B. Lurie, to initiate the 1993 planning process.

Because the size of the annual meeting has increased, fewer than a dozen cities have the facilities—both sleeping and meeting rooms—to meet our needs, and these cities are heavily booked. As an example, we cannot obtain space in Chicago or San Francisco until after the year 2000. Thus, we must plan considerably ahead to ensure having the location we want at a time that meets our needs, recognizing that external events may change during this longer lead time. The schedule, as planned, is as follows:

- 1993 San Francisco
- 1994 Philadelphia (Sesquicentennial)
- 1995 Miami
- 1996 New York City
- 1997 San Diego
- 1998 Toronto

The accomplishments of the annual meeting could not have taken place without the devoted efforts of staff. In particular, I would like to recognize Ms. Carol Davis, who has provided oversight and support, as well as her special know-how and experience in so many areas; Mr. George Campbell and staff of the Office of Meetings and Exhibits Management, who have been immensely helpful and whose professionalism has contributed to the positive tone and format of the meeting; Ms. Cathy Nash, Director of the Office to Coordinate the Annual Meeting, and her staff, whose remarkable efforts have provided a smooth, highly organized program; and Dr. Robinowitz, who provides overall supervision. Their creativity, hard work, and resilience enable us to handle this complex, multifunctional large-scale event in a way that provides an opportunity for each attendee to have an enjoyable and useful educational and social experience.

We have reviewed the recently approved guidelines of the Accredi-

tation Council for Continuing Medical Education regarding interactions with industry and have discussed these regulations with the Committee on Exhibitors and Advertisers and with additional representatives of industry. Our planning, review, and evaluation procedures are in compliance with the guidelines of the Accreditation Council for Continuing Medical Education, and we have strengthened the involvement of the Scientific Program Committee with the symposia faculty to ensure broad and representative scientific content throughout.

The Scientific Program Committee, recognizing the concerns about quality and control of industry-sponsored educational activities, continues to review and monitor these efforts closely. Members were pleased with what appeared to be the impact of the discussions held during two meetings with industry representatives this past year. Not only is duplication of topic or presenters absent but the sessions are more broadly based, with less overemphasis on pharmacological issues. A clear effort is being made to address Dr. Hartmann's theme of biopsychosocial integration. Notwithstanding this improvement, the Scientific Program Committee this year did reject several industry-sponsored submissions because they did not meet the rigorous scientific and educational criteria for inclusion in the program. The committee also plans to monitor adherence to the guidelines related to publicizing such sessions and any associated social activities.

An example of the need to oversee relations with industry occurred in November 1991, when we met with representatives of Glaxo Pharmaceuticals regarding its videotape of the forum on managed care presented at the 1991 annual meeting. We were unable to obtain funding for this task, and Glaxo volunteered to make and distribute videotapes of the session. There was considerable delay in proceeding because Glaxo expressed concern about the quality of the product, stating that it was a very one-sided, unbalanced session of simply “bashing” managed care. At the same time, the moderator was quite concerned that the tape was not being produced quickly enough and that it appeared Glaxo was interfering with our judgment about the content of the session. As these concerns were clarified, Glaxo reiterated its willingness to support editing of the tape according to APA specifications and to make clear that the tape and the session from which it was derived were APA's responsibility. We especially appreciate the input and assistance of Dr. English in resolving the conflicts and moving the process along. Dr. Robert Michels, who moderated the original session, and Dr. Ellen Leibenluft from the Scientific Program Committee have completed their review, and the final product is in preparation.

The 1991 Institute on Hospital and Community Psychiatry, held in October in Los Angeles, was a great success by any standard. It exceeded expectations programmatically and fiscally, with more than 250 program offerings and over 1,500 registrants. Under the leadership of Dr. Harold Eist, the Institute on Hospital and Community Psychiatry Program Committee developed an extensive array of enriching offerings on clinical and policy topics. Of special interest were sessions on women, the interface of cardiology and psychiatry, and treatment planning.

The 1992 Institute on Hospital and Community Psychiatry Program Committee, chaired by Dr. David Olenik, met in early January to plan the 1992 institute, to be held in Toronto, Friday, Oct. 23, through Tuesday, Oct. 27. For the first time, the meeting will be held over a weekend to take advantage of reduced air fares. Its theme, “Partnerships for Mental Health: Access, Quality, Cost,” reflects the interests of APA leadership as well as Canadian and consumer representatives.

Full- and half-day sessions will be held on such topics as administrative psychiatry, international mental health programs, the Canadian mental health system, universal access to care, managed care, schizophrenia, substance abuse, AIDS, multiple personality disorder, therapist-patient relationships, and a host of other clinical issues.

We have also begun recruitment of the next group of APA/Mead Johnson Fellows. Eligible are residents who enter the third postgraduate year during the fellowship year. This program strives to heighten residents' awareness of opportunities in the public sector, enhance their training experiences, and familiarize them with programmatic aspects of APA.

We also have been most impressed by the continued growth and excellence of the *Hospital and Community Psychiatry* journal. Dr. John

Talbott's energetic and effective editorial efforts have served the field well. The excellent staff support of Managing Editor Ms. Teddye Clayton and her staff has maintained smooth functioning even during Dr. Talbott's sabbatical.

Last year Dr. Lewis Judd resigned as Director of the National Institute of Mental Health (NIMH) to return to the University of California. During his tenure Dr. Judd displayed great wisdom and effective leadership, increasing both the funding and the prestige of NIMH and the profession. Dr. Judd, in collaboration with the National Mental Health Association, initiated the National Mental Health Leadership Forum, whose members represent major professional organizations and advocacy groups. This forum, in conjunction with the National Advisory Mental Health Council, has held town meetings and hearings, which have been most effective in addressing needs and combating stigma; they have strengthened the planning process for access to and organization of care. The forum's work on public information and image is outstanding. I also would like to express appreciation for the work of Dr. Alan Leshner and his service as NIMH Acting Director during the past year and a half. He has done much to continue the excellence of the institute.

While the saga of the proposed legislative reorganization of the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) and the need to protect the integrity of NIMH research and services continues, it was, and will continue to be, deeply influenced by the resignation of Dr. Frederick Goodwin from his position as Administrator of ADAMHA. Dr. Goodwin resigned as ADAMHA Administrator in response to what we told Dr. Lewis Sullivan, Secretary of the U.S. Department of Health and Human Services, was a "racially insensitive and inappropriate comment about violent behavior," which he made to the National Advisory Mental Health Council at its meeting on Feb. 11, 1992. At the same time, we supported Secretary Sullivan's decision to appoint Dr. Goodwin as NIMH Director because "it would be wrong to punish the mentally ill citizens he has served so well." The National Alliance for the Mentally Ill told Secretary Sullivan that their 150,000 family members commended Secretary Sullivan for Dr. Goodwin's appointment. APA member Dr. Joseph Coyle (President of the Society for Neuroscience and chairperson of the Department of Psychiatry at Harvard Medical School) told Secretary Sullivan that Dr. Goodwin is "an eminent neuroscientist and internationally-recognized psychiatrist who has provided outstanding leadership at ADAMHA." Moreover, while many leaders (including those at the American Psychological Society) supported Secretary Sullivan's decision to name a psychiatrist as Director of NIMH (neither ADAMHA nor any of its other institutes is headed by a psychiatrist), the American Psychological Association actively opposed Dr. Goodwin's appointment.

We all were distressed with the events leading to the resignation and with the impact on the field. Other related serious political and policy consequences, fueled by the controversy surrounding Dr. Goodwin, include the impact of the foregoing on the reorganization of ADAMHA and how to protect the present (tripartite) mission of NIMH because of the essential connection between services and research, scientifically designed demonstration projects, and sophisticated basic biological, behavioral, clinical, and epidemiological research.

Last year the U.S. Senate approved reorganization legislation, placing the research activities of the institutes under the jurisdiction of the National Institutes of Health while maintaining a separate services program under the jurisdiction of the proposed "Alcohol, Drug Abuse, and Mental Health Services Administration." Key members of the House of Representatives initially expressed reservations about the reorganization. At this writing, it appears that the issue was resolved in a House-Senate conference and that the transfer and reorganization are slated for October 1992. We will need to monitor plans and their possible impact closely, and we anticipate working with the academic and consumer communities to ensure the best possible outcome.

The issue of managed care continues to be of great concern to our members. The variations in perception and concerns expressed has been striking. Intrusiveness, the "hassle factor," and awareness of some groups' egregious practices in denying care to those in need are voiced most commonly. At the same time, many APA members work in managed care settings and organizations; some have expressed

strong dissent, noting that APA has not been sufficiently responsive to their concerns and interests, stating that they too are working to promote quality and cost-effective care. Our activities in this arena are broad and varied, and we will continue to support efforts to ensure quality and appropriateness of care. This task has been an interdepartmental staff effort, involving the Office of Psychiatric Services, the Division of Government Relations, the Office of Economic Affairs, and the Division of Public Affairs, working with the Committee on Managed Care, chaired by Dr. Steven S. Sharfstein. We have developed model legislation for standards of managed care, which will be an important resource for individual states. We have met with psychiatrists who hold leadership positions in the managed care industry and have shared members' concerns about practices that interfere with appropriate care.

We have organized meetings with managed care companies to initiate dialogue addressing these problems and provided information to district branches who work with state insurance commissions regarding the need for regulation of utilization review companies. The Division of Government Relations is working to assess the effect of state utilization review legislation, and the Committee on Managed Care is implementing the managed care district branch network.

Staff continues to analyze documented cases reported through the 800 telephone number to assess trends and problem areas. Case information is supplied to district branches for use in negotiations with state insurance commissions regarding the need for regulation of utilization review companies and in monitoring the effectiveness of existing legislation.

Utilization Management: A Handbook for Psychiatrists was mailed to district branches in early spring. Its goal is to educate members in the process of managed care and utilization review. A press conference was held in February to announce the handbook and the *Manual for Psychiatric Quality Assurance* as two of APA's newest efforts in managed care. We continue to collect the medical necessity criteria used by managed care organizations and are developing a criteria library in the Office of Economic Affairs to facilitate review and evaluation of such criteria by the Committee on Managed Care in conjunction with the Committee on Quality Assurance.

The Utilization Review Accreditation Commission, on which APA has board representation, issued its first *National Utilization Review Standards*. These include procedures for review determination, appeals, and confidentiality; staff and program qualifications; and the process for accreditation by the Utilization Review Accreditation Commission.

We also are continuing to document problems with state Medicare carrier operations and are interacting with the U.S. Health Care Financing Administration regarding overall policy, as well as with individual district branches for negotiations with local carriers.

Work is under way to update the *Coverage Catalog*, which will include information about managed care features in employee health plans, and to update the information in the *Marketing Manual*, with a new section on marketing medical psychotherapy. An article on clinical marketing is under development.

In each annual report, I have given special emphasis to our activities in government relations and public affairs. This year is no exception; indeed, I still rate these as the highest-priority areas for producing genuine advances in diminishing stigma while increasing access to and reimbursement for care. Working in concert with our Joint Commission on Government Relations, Dr. John J. McGrath, chairperson, and with commission members and network leaders, the Division of Government Relations continues to function as a sophisticated, effective force.

From my perspective, during this past year we have been much more visible and successful in our government relations activities than ever before. We have begun to develop clear and concrete objectives that have had an enormous impact on members and the patients they treat. We are most fortunate to have Mr. Jay Cutler leading our government relations efforts. He is widely respected on Capitol Hill and in the Administration, as well as by his colleagues. Our successes are a credit to his energy and knowledge and to the long-range strategic planning and involvement of the field in Congressional communications.

The President's State of the Union message contained a strong and politically partisan tone, reflected in the work of the second session

of the 102nd Congress, which already is demonstrating election-year stresses through an unusually partisan climate of debate.

The prospects for health care reform are complex. The Senate Finance Committee approved very limited reforms, targeted at small-market health insurance; the Senate Labor and Human Resources Committee, which already approved the Mitchell-Kennedy "pay-or-play" plan, is expected to consider small-market reform legislation. Similar action is expected by the House Energy and Commerce Committee and the House Ways and Means Committee. These deliberations mask deep-seated disagreements about the scope and direction of health care reform, most particularly as to whether to take limited action aimed at the small market or to risk confrontation with each other and the White House over broader national reforms.

At the same time, it is essential to appreciate political reality; health care reform has so far proved easier for federal legislators to debate than to enact, since support has yet to coalesce around a single legislative proposal. The President's plan includes incentives to encourage Medicare and Medicaid beneficiaries to enroll in managed care plans; limited tax incentives for the purchase of health insurance; medical liability reforms; insurance industry reforms, including preemption of state benefit mandates and state regulation of anticonsumer managed care and utilization review practices; and a sweeping restructuring of the Medicaid program. APA cannot endorse this plan, as it would undercut the strides made in mandating mental health benefits and curbing abusive managed care practices. The Mitchell-Kennedy "pay-or-play" plan, while approved by the Senate Labor and Human Resources Committee, has little support outside of Congress. It is opposed by the insurance industry, and President Bush is reportedly prepared to veto it should it be approved. Intense activity can be expected as both political parties jockey for position as they head into the 1992 national elections.

APA has managed to ensure that most of the key proposals for health care reform include at least some coverage of psychiatric services. The coverage is limited in scope and duration because of Congressional perceptions (fueled by small businesses and the insurance industry) that coverage of psychotherapy and counseling provided by the broad range of mental health professionals included under each state's scope of practice and licensure laws is not necessarily a basic necessity or medically necessary service.

In a related development, APA is working with Representative Mike Kopetski (D-Ore.), a founder of the Congressional Mental Illness Task Force, to develop a Sense of Congress resolution, noting the needs of the mentally ill and stipulating that any comprehensive health care reform legislation include comparable coverage for mental health care. APA also has urged the repeal of the discriminatory 50% copayment requirement for outpatient mental health care under the Medicare program.

The new Medicare fee schedule, based on the resource-based relative value scale (RBRVS), went into effect on Jan. 1, 1992. APA launched a massive and successful effort to correct major errors affecting psychiatry, as published in the June 1991 RBRVS Medicare fee schedule proposed by the Health Care Financing Administration (HCFA). APA work on the RBRVS is ongoing, under the leadership of Dr. Donald Scherl; despite the improvements in the final Medicare fee schedule for psychiatry relative to the 1991 report, many problems remain. APA's most recent comments were filed in late March. Despite this general success, APA members may be adversely affected by several other factors, most notably the geographic adjustment for payments to physicians practicing in relatively high-cost urban areas. We have undertaken a massive educational effort for our members, which will continue as the process evolves. Additionally, the RBRVS work group, consultants, and individual APA members continue to identify and highlight remaining problems adversely affecting psychiatry.

The final version of the fiscal 1992 ADAMHA appropriations bill has been signed into law. NIMH research funding received a 10.9% increase over fiscal 1991. All NIMH programs in the aggregate received a 9.5% increase over fiscal 1991, a significant victory for APA advocacy. The Bush Administration's proposed fiscal year 1993 budget would provide for a \$184 million increase in total ADAMHA funding over fiscal year 1992, with a \$62 million increase in research funding, a \$21 million increase in funding for substance abuse prevention, and a \$4 million increase in demonstration project funding.

We are working with other mental health organizations to develop recommendations for ADAMHA appropriations for fiscal year 1993.

We have submitted comments to the Office for the Civilian Health and Medical Program of the Uniformed Services (OCHAMPUS), addressing proposed reauthorization requirements for mental health services under CHAMPUS, new statutorily reduced inpatient and residential treatment center limits, and a proposed new psychiatric partial hospitalization program benefit. We opposed implementation of the preauthorization program before the October 1991 statutory mandate. We argued that CHAMPUS must better recognize and emphasize the role of psychiatrists in the delivery, authorization, and review of CHAMPUS benefits. APA's comments particularly focused on the critical role of the psychiatrist in the inpatient setting. We strongly supported the new CHAMPUS psychiatric partial hospitalization benefit. Citing APA experience in working with the HCFA on the Medicare partial hospitalization program, we offered to work with OCHAMPUS to better define the parameters of the program.

We urged withdrawal of proposed regulations that would remove existing CHAMPUS medical supervision and referral requirements for marriage and family therapists, mental health counselors, and pastoral counselors. If implemented, this proposed regulation would vitiate any requirements for medical necessity of care and treatment and, further, ignore the need for medical differential diagnosis of CHAMPUS patients or even any evaluation by mental health professionals at the level of a licensed clinical psychologist or clinical social worker. Finally, we noted that it was inappropriate for OCHAMPUS to usurp the traditional state role in regulating the professions by promulgating new federal criteria.

No action was taken in 1991 on legislation introduced by Representative Gary Ackerman (D-N.Y.) to reform the Federal Employees Health Benefits Program, although Representative Ackerman has stated that the House Post Office and Civil Service Committee will hold hearings on the proposal later this year.

APA efforts to ensure that Medicare supplemental insurance ("Medigap") plans cover the current 50% beneficiary copayment for Medicare outpatient mental health treatment have produced a major victory. The Omnibus Budget Reconciliation Act 1990 budget bill required the National Association of Insurance Commissioners to revise uniform minimum standards for Medigap insurance policies. The model standard would, among other provisions, require all Medigap policies to cover the Medicare 50% copayment for outpatient mental health care. I wrote to the National Association of Insurance Commissioners, commending them for their action to end discrimination against the mentally ill and urging them to widely publicize the coverage requirement. In January I also wrote to HCFA Administrator Ms. Gail Wilensky to urge that the HCFA make certain that the mandatory coverage requirement is explicitly stated in forthcoming regulations. On Feb. 21 APA received a response from Mr. Robert G. Eaton, Acting Administrator for Program Development, noting that the HCFA and the National Association of Insurance Commissioners agree that "a Medigap policy must pay the coinsurance for Part B services, which in the case of certain outpatient psychiatric services is effectively 50%." This letter attests to the success of our efforts to end this aspect of discrimination against mental illness treatment.

Intensive efforts helped defeat a last-minute surprise effort to amend the Medicare part A hospital conditions of participation to permit clinical psychologists to supervise care of hospital inpatients. The amendment, authored by Representative Pete Stark (D-Calif.) was felt to be needed because the HCFA allegedly had threatened several hospitals in California with decertification for violating Medicare rules by giving psychologists the right to admit and discharge patients without any physician involvement; the hospitals were responding to the *CAPP v. Rank* decision. At least one of the two hospitals has since changed its rules to avoid conflict with Medicare regulations. Our staff-to-staff contacts brought us an otherwise unavailable document and enabled the Association to voice strong objections to the clinical psychologist provision contained in this amendment. APA argued that it was not technical in nature, that it would have a profound impact on hospital admitting and staffing practices throughout the nation, and that it was yet another attempt to achieve by federal fiat the "medicalization" of psychology. In particular, we argued that it would improperly affect debate in the California legislature to clarify the intent and scope of the *CAPP v. Rank*

ruling. With the vigorous support of the California and Texas district branches, we helped persuade the Senate to defer action on the technical corrections legislation. We expect that Senator Jay Rockefeller (D-W.Va.) will offer the amendment when the Senate Finance Committee considers the bill. Prospects for defeating the amendment are not good, given past Finance Committee support for clinical psychologist legislation.

Four clinical psychologists are in their first year of training at the Uniformed Services University of the Health Sciences under the U.S. Department of Defense psychologist prescribing demonstration program. They are studying gross anatomy, biochemistry, and physiology as part of their first-year didactic program. As part of their patient care training, each psychologist will be expected to "manage," under supervision, 100 psychiatric patients at Walter Reed Army Medical Center. At no time will they be permitted to prescribe independently. Informal reports suggest that some of these trainees are having difficulty with the content of the program and are being permitted to audit the medical courses and are excused from the oral and written examinations required of the medical students.

The fiscal 1992 Department of Defense appropriations bill passed by the House of Representatives included committee language that stated that the program "is only a demonstration, and the Department [of Defense] should not plan any follow-on program or utilization of these individuals to prescribe drugs without written approval of the Congress." In contrast, the Senate version of the defense appropriations bill noted that the "committee feels strongly that this program should be allowed to continue with prohibitions." The final conference report on the compromise bill noted only that the "conferees support the bill language contained herein providing for a two-year prototype drug prescribing training program of military psychologists at Walter Reed Army Medical Center."

The House of Representatives has repeatedly sought to limit the Department of Defense demonstration program but has been unsuccessful, chiefly because Senator Daniel Inouye (D-Hawaii), the program's chief proponent, is the chairperson of the Senate Defense Appropriations Subcommittee and thus is in the key position to ensure survival of this program.

The Senate version of the fiscal 1992 defense appropriations bill included a requirement that the Assistant Secretary for Health Affairs report on "the extent to which military psychologists are currently provided hospital privileges (admitting, discharge, and treatment privileges)" and stated that the "Committee feels that a uniform policy (on admitting) would be more appropriate and further urges the Secretary to institute a permissive policy." The House version of the bill responded to APA advocacy and included no such report requirement or statement of concern about admitting privileges. The Senate language was dropped in the final conference report.

Legislation permitting psychologists to have hospital privileges was introduced in nine states: Louisiana, Massachusetts, Michigan, New Jersey, New York, Ohio (enacted), Pennsylvania, Texas, and Wisconsin. The California legislature continues to struggle with efforts to clarify the *CAPP v. Rank* ruling.

Although no final action was taken in 1991, the Senate Labor and Human Resources Committee and the House Education and Labor Committee each approved legislation (S. 1150 and H.R. 3553) to reauthorize the programs of the Higher Education Act. In a move that stunned the entire medical community, both committees sought to end the current 2-year deferment of repayment of student loans by medical residents, effective Oct. 1, 1993. This unpublicized action allegedly stemmed from committee efforts to obtain paper savings to offset spending elsewhere in the budget.

APA joined with other medical specialty societies, under the auspices of the American Medical Association (AMA), in sending a letter to Congress urging that the termination of the 2-year deferment be rejected. We also sent an "Action Alert" to directors of residency training programs, chairpersons of departments of psychiatry, psychiatry residents, and Medical Student Members, informing them of the proposed change in policy and urging that they inform federal elected officials of their opposition. Numerous letters have been sent to date. The Senate considered the bill in late February and agreed to permit continuation of the 2-year deferment but only for student loans taken before July 1, 1993. House action is expected this month.

We are very pleased that both the House and Senate have approved

legislation incorporating parts of APA recommendations regarding international medical graduates (IMGs). Both bills would establish an Advisory Council on Medical Licensing to monitor the AMA's proposed private system of credentialing IMGs. The advisory council is to report by 1996 on whether the private system is operating effectively. If the AMA's system is not operating effectively, a national system may be established in its place.

We also are pleased at the AMA's efforts with state licensing boards, state and county medical associations, and specialty societies to assist them in developing a strong infrastructure for IMGs and to integrate our concerns into their overall agenda and lobbying efforts.

In December we learned that the AMA had awarded a small grant to APA to support mini-forums on the principles of the AMA Health Access America plan, in conjunction with Area council meetings. The program, which in no way implied endorsement of the Health Access America plan, was designed to foster dissemination of information about the AMA plan for universal access to APA leaders and support dialogues between members and Area business leaders. These sessions provided an opportunity for greater education on issues faced by business and industry in providing health benefits and offered an opportunity to interact with business and industry leaders to inform them about the need for mental health care and problems with access to such care.

APA's representation in the AMA House of Delegates has been forceful and effective. Delegate Dr. John McGrath and Alternate Dr. Ronald Shellow have worked with the Section Council on Psychiatry and with other members of the House of Delegates to support ideas and resolutions. Dr. Richard Steinhilber, through his membership on the AMA Council on Scientific Affairs, has been able to influence areas of AMA scientific investigation. We were pleased that Dr. Douglas Skelton was elected to that council. The representation of the American Academy of Child and Adolescent Psychiatry in the House of Delegates and representation of APA and the American Academy of Child and Adolescent Psychiatry in the Resident Physicians' Section and Young Physicians' Section have been most productive.

While all of APA's suggestions regarding the *Physicians' Current Procedural Terminology (CPT)* are still to be accepted, our input (with the substantial support of Dr. Tracy Gordy, who was appointed to the AMA CPT Editorial Panel, and assistance from Dr. Chester Schmidt) resulted in acceptance of three new interactive therapy codes for the 1992 CPT. We have developed sample vignettes dealing with levels of service for use with the evaluation and management codes, now being reviewed by the CPT Editorial Panel. (An educational packet including information on the new evaluation and management codes, the new interactive psychiatric medical codes, and the psychiatric examples of the new outpatient and inpatient visit codes has been developed for distribution to members.)

I was delighted to be appointed to a special advisory committee to Dr. James Todd, AMA Executive Vice-President; this participation allows for considerable ongoing communication and supports the continuation of our positive and effective interactions with AMA staff.

In late February we held the first combined Public Affairs and State Legislative Institute, which was highly successful. The more than 300 participants expressed much satisfaction with the format and content and encouraged future joint programs. We received funding from almost two dozen pharmaceutical companies, thanks to the efforts of Mr. Ray Purkis, Director of Advertising Sales. Participation by leaders in state legislatures, the insurance industry, the media, and other medical specialties was excellent. The sessions covered such topics as managed care, access to care, prescribing by psychologists, psychiatry's image, and work with the media. The institute offered hands-on skill-building experiences. We congratulate Mr. Jay Cutler, Mr. John Blamphin, and staff in the Divisions of Government Relations and Public Affairs for providing this excellent learning opportunity and meeting the demands of coordinating these sessions.

APA is again working with Senator Paul Simon (D-Ill.) and Representative Ron Wyden (D-Ore.) to introduce this year's Mental Illness Awareness Week resolution. This excellent example of the best in staff interdepartmental functioning and national-local collaboration has become both year-long and international in scope. I would like to commend especially Mr. Cutler and Ms. Phyllis Greenberger for their continued success in this important arena. For the 1991 Mental Illness

Awareness Week, the Division of Public Affairs developed an array of public information materials for journalists and clergy, as well as providers and consumers. District branches conducted public information campaigns in almost every state. The "hometown" radio broadcasts reached a huge audience. Dr. Harvey Ruben conducted a special national 3-hour "Talknet" program with special guests that included Ms. Rosalynn Carter, Dr. Elissa Benedek, and Dr. Lawrence Hartmann.

We have been quite involved in public affairs functions. In his capacity as chairperson of the Joint Commission on Public Affairs, Dr. Harvey Ruben has provided energetic and wise leadership over the years, working closely with Mr. John Blamphin, who heads our staff division. Dr. Ruben's tenure as chairperson concluded this May. He is being honored by the National Mental Health Association for his effective vision and leadership in public education. We also look forward to our work with the incoming chairperson, Dr. Edward Hanin. Collaborative projects with industry have helped enhance psychiatry's image with other physicians and the public. The joint effort with the Upjohn Company has supported several activities. The third film produced in this venture, "Depression: The Storm Within," premiered last year at the American Film Institute Theater at the Kennedy Center in Washington, D.C. Recipient of a prestigious CINE Golden Eagle award from the Council on International Nontheatrical Events, it has been extremely well received by viewers—psychiatrists, other health and mental health professionals, and laypersons. The other two films and related campaign materials have been designed to convey such messages as mental illnesses are real illnesses that cause pain and disability to millions of Americans; they can strike anyone; and they can be diagnosed accurately and treated effectively. The messages also clarify who psychiatrists are and what they do, as well as emphasize the impact of scientific advances. All three films have been seen by nearly 1.5 million people nationwide.

We also have reached over 10,000 physicians and other health professionals through workshops on panic disorders. The materials include an educators' guide to mental illness awareness that suggests curricula, provides camera-ready materials, and identifies local APA contacts. The comic book "Let's Talk About It," designed for junior high and high school audiences, has been well received by more than 64,000 teachers and students. Similarly, we have distributed almost a million products (e.g., pamphlets, posters, bookmarks) related to the "Let's Talk About Mental Illnesses" campaign. The Division of Public Affairs has responded to requests for information about mental illnesses and psychiatric treatment and has provided pamphlets on such topics as anxiety, mental illness, depression, and choosing a psychiatrist.

The Public Affairs Network is one of several locally based groups that expands the reach and effectiveness of the Central Office. Other networks relate to government affairs, AIDS, economics/managed care, research, and education (through chairpersons of departments of psychiatry and directors of residency training in psychiatry). They have been important in such efforts as Mental Illness Awareness Week and providing information to Congress and other policymakers. We now have an experienced network of trained leaders who can cope effectively with all varieties of media.

Work on *DSM-IV* has proceeded remarkably well, and Dr. Harold Pincus, Dr. Allen Frances, and staff have been quite productive. Draft criteria for each proposed diagnostic category have been developed and are contained in the *DSM-IV, Work in Progress: Options Book*, which has been distributed widely to members, components, and the Assembly; additional copies may be ordered from the American Psychiatric Press. The book includes a tear-out form for comments, and the field has been invited to send suggestions and comments on any aspect of the options to the APA Office of Research. With funding from the three ADAMHA institutes, we are conducting field trials at multiple sites to assess specific nosologic issues. A grant from the John D. and Catherine T. MacArthur Foundation funds the analysis of data sets that address unresolved issues for *DSM-IV* and the videotape field trial project. Several videotapes will be pilot tested during the video program at this annual meeting. The draft literature reviews on diagnostic issues are being compiled for inclusion in a *DSM-IV* "source book," to be available later this year. Staff has been involved in discussions with the World Health Organization (WHO), NIMH, and the National Center for Health Services to assure compatibility be-

tween *ICD-10* and *DSM-IV*. A conference involving APA and WHO, sponsored by NIMH, is planned for early July.

In keeping with our increased involvement with colleagues in other medical specialties, we have met with representatives of several organizations to discuss the adaptation of *DSM-IV* for primary care physicians. We anticipate that a preliminary draft of the primary care version of *DSM-IV* will be available in 1993.

During the November 1991 Assembly meeting, we received notice of a petition asking APA to vote on a referendum concerning the adoption of *ICD-10*, upon its publication, as the official psychiatric classification system in the United States and delaying the publication of *DSM-IV* at least until 1997. Initially there appeared to be more than the requisite 500 signatures of voting members; however, a review of the actual signatures demonstrated that, because of duplication and listing of some nonmembers and nonvoting members, the petitioners were 43 signatures short. We informed the petitioners and gave them time to produce the additional signatures, but they were unable to do so. Consequently, the item was not on the 1992 ballot, but it may be resubmitted for next year.

As always, I am concerned about the scientific and policy effects, as well as fiscal implications, of such a referendum. While the latter are obvious, in the long run the impact on science and policy may be extremely deleterious. Arbitrary nonscientific, nonclinical decisions do not enhance the field, and such determinations should not be made by popularity or comfort, but rather by evidence.

Congratulations are due Dr. Pincus for his success in obtaining significant funding to support research and field trials related to *DSM-IV* and funds from the van Ameringen Foundation for activities designed to improve recruitment, training, and retention of psychiatrist researchers. He and his staff also are to be commended for their publication of numerous journal articles.

I am pleased at the progress of the NIMH-funded Program for Minority Research Training in Psychiatry, now in its third year, which is administered by the Offices of Research and Minority/National Affairs. In late February eight postresidency fellows were accepted for 1 year of support; five already have completed a year of research training through this program. We also have selected "mini-fellows" to attend the 1992 annual meeting. Once again, the program will include a variety of scientific and mentoring activities.

Dr. Pincus and his staff have received much praise from the field for the quality of *Psychiatric Research Report*. This quarterly newsletter provides considerable information about science policy, funding and educational opportunities, and research programs.

Dr. Pincus, Dr. McIntyre, and Office of Research staff have been very productive in a variety of activities related to practice guidelines. Drafts of the guidelines on eating disorders and major depression have been distributed to over 100 reviewers and consultants. The eating disorders guideline was considered at the May Assembly and June Board of Trustees meetings. (The guideline was approved by the Assembly and the Board.) Work groups for the guidelines on inpatient evaluation and outpatient evaluation have been established; the initial draft of the outpatient guidelines was reviewed at the January meeting of the Steering Committee on Practice Guidelines. Our efforts to obtain NIMH funding for this work have been fruitful; the funds will be particularly useful in supporting staff work and the track II development. Using this grant, Dr. Pincus has recruited a psychiatrist who will take on the staff responsibility for practice guidelines within the Office of Research, working with Dr. McIntyre and the steering committee. We also continue to participate in the AMA Practice Parameter Partnership and Forum. There is substantial interest in practice parameters (standards and guidelines) within organized medicine. The Council of Medical Specialty Societies sponsored conferences on standards development, and the AMA has undertaken a major initiative for specialty societies to address the topic. Drs. John McIntyre and Sara Charles represented APA in these efforts. I am optimistic and enthusiastic about working with other medical specialties on this important project and about the potential impact of such endeavors on the field.

The Office of Survey Design and Analysis has prepared a series of tables describing findings from the Professional Activities Survey. Staff are engaged in a variety of activities focusing on psychiatrists in research and characteristics of psychiatrists who treat alcohol-related disorders.

There continues to be considerable interest in the APA governance process. The increased activities of the Assembly Executive Committee and its evolution as a major force in the governance of the Association were reflected in its interim meeting in September 1991, in the fourth highly successful meeting with the Joint Reference Committee in February 1992, and in its expanding role in assisting the Assembly in planning and implementing actions.

The Joint Reference Committee, too, has strengthened the input of its voting members while maintaining the importance of the participation of council chairpersons and emphasizing its "joint" role, representing both the Assembly and the Board. The Joint Reference Committee increasingly acts not simply as a referring body but also as initiator and developer of proposals and directions. Drs. Hartmann, Pfahler, English, Shellow, and Bridburg are to be congratulated for their thoughtful yet pragmatic approach to both issues and processes. Ms. Corky Hart has been a marvelous resource here, and the outstanding involvement and coordination of Ms. Jeanne Robb and staff in the Office to Coordinate the Board and Assembly make the process work smoothly.

Discussions about the roles of officers and trustees emphasize the increased involvement and interest of Board members, as well as the expanded amount of business on the agenda of each meeting and the need to set aside time for reflection and strategic planning for the Association. This interest is reflected in the ongoing discussion about subspecialization and liaison activities by the Assembly and Board Commission on Subspecialization. The American Board of Psychiatry and Neurology (ABPN) has responded positively to our recommendations to initiate the process for offering certificates of added qualifications in addiction psychiatry and forensic psychiatry. The American Board of Medical Specialties has formally approved added qualifications in addiction psychiatry and is currently reviewing added qualifications in forensic psychiatry. The Commission on Subspecialization, chaired by Dr. James Trench, is considering the request for added qualifications in consultation-liaison psychiatry. We remain cognizant of the potential fragmentation and divisiveness of such efforts and the need to maintain organizational strength while maximizing input from all concerned.

The significant number of members who vote in elections for APA officers and trustees is most gratifying. We remain one of the few large national organizations that conducts a contested election with voting open to the entire membership; our colleagues in other specialties and disciplines continue to voice their amazement that 40% of eligible members vote in the election. The election process is an enormous task for a group as large as ours, and I am impressed by Ms. Carol Lehmann's careful attention to detail and mastery of the multiple issues that must be considered to ensure a fair and accurate election. The process this year was complex, and I especially appreciate the attentiveness of Elections Committee members to compliance with our guidelines.

Last year, immediately after the annual meeting, APA held a joint meeting with the Caribbean Psychiatric Association. Although the participants' response to the meeting was very positive, it was the last such joint meeting. Increasing demands for higher-priority activities coupled with diminished resources make such meetings impractical.

The substantial increase in communication with psychiatrists in Eastern and Central Europe and with the countries of the former Soviet Union led to our very successful bilateral educational project in April. Under the aegis of the Council on International Affairs and funded by a grant from the Upjohn Company, the project funded a group of psychiatrist experts who traveled to Poland, Hungary, and Czechoslovakia, giving lectures, participating in educational exchanges, and donating books and journals to psychiatrists in these countries. We were impressed by the intellectual fervor with which these sessions were greeted and very much appreciate the leadership of Dr. Eugene Feigelson, chairperson of the Council on International Affairs, and the remarkable efforts of staff member Ms. Ellen Mercer to make this complex endeavor so fulfilling. I also am pleased with Ms. Mercer's participation in the Romania Strategy Group, organized by the U.S. Department of Health and Human Services to coordinate the efforts of American organizations working in Romania. Although the needs of children are being attended to by many groups, there has been no evidence that the mental health needs of the population are being addressed comprehensively by American organizations other

than APA. My own visit to Bulgaria was most enlightening, demonstrating the impact of the massive political change on delivery of psychiatric care and the need for our substantive ongoing involvement. Our Office of International Affairs has gained wide respect under the leadership of Ms. Mercer, and this remains a source of special pride and satisfaction. This office provides assistance for psychiatrists in this country and abroad on issues involving education and trans-cultural practice and care.

I was delighted to learn that we will receive a federal contract of approximately \$25,000 for our Hispanic data base project. The advisory committee, chaired by Dr. Fernando Milanes, will be developing a work plan and a survey instrument. Our goal is to prepare a directory of agencies and practitioners engaged in mental health, substance abuse, and social services for Hispanics. The directory will have three parts: Hispanic psychiatrists who are APA members, Hispanic psychiatrists who are not APA members, and agencies. We will use an approach similar to that used in gathering data for the directory of Asian-American psychiatrists. This is an important effort to address the interests and needs of our members and the populations they serve.

Staff in the Office of Minority/National Affairs have been active in many areas, providing voice, support, and recognition of minority issues and issues affecting children and their families. Contributions to the residents' fellowship programs have been especially meaningful to these colleagues and to those of us who interact with them. Dr. Spurlock also has been involved in liaison efforts dealing with medical, mental health, and advocacy groups and has been a most effective spokesperson for the Association.

We continue to maintain active interaction with the leadership of the American Academy of Child and Adolescent Psychiatry. Additionally, Drs. Pincus and Robinowitz continue to be involved in activities related to research and training in child and adolescent psychiatry. Dr. Henry Work assists staff working on child psychiatric activities one-half day a week and oversees our liaisons. We continue to be concerned about recruitment, retention, education, and clinical care, as well as research and research training, in this important area.

I am very pleased that the Kenworthy-Swift Foundation approved our request for a \$25,000 grant to support the work of the Task Force to Study the Use and Abuse of Psychiatric Hospitalization of Minors. Dr. Elizabeth Weller, chairperson of the task force, will consult with staff to define the work plan.

On Jan. 1, 1992, our membership totaled 37,279, for a net gain of 361 during 1991. The number of non-dues-paying members continues to increase faster than the number of dues-paying members. The increase in losses in 1991 resulted in large part from the change in policy that required dropping members who were in arrears for 1990 dues in June 1991 (as opposed to December 1991); there was also a slight decrease in the number of new members. Reinstatements were higher in 1991 (31 more than in 1990). Non-dues-paying members represent 19.5% of the total. Medical Student Members and Members-in-Training total 17.6% of our membership, as compared to 15.6% in 1987. Over the past decade the APA membership increased from approximately 26,000 to 37,000, for an average net gain of about 1,000 members a year. It is apparent, however, that this growth, related in part to the increase in medical students choosing psychiatry (following the 1980 recruitment conference and related efforts) and to our success in recruiting Members-in-Training, has begun to level off. Only Areas I and VII registered gains in membership in 1991-1992. We have engaged in a number of recruitment efforts aimed at women psychiatrists and child psychiatrists who have never been members. We continue efforts to recruit nonmember ABPN diplomates as well. We have completed the data analysis for the 1990-1991 annual census of residents in psychiatry. The number of residents stabilized at almost 6,000, and 681 medical students are members. Analysis of the members who have been dropped demonstrates overrepresentation in some areas, i.e., certain district branches have a higher proportion of drops/resignations than their proportion of membership warrants. Additionally, the largest number of Members-in-Training who were dropped were in their third year; at that time the Members-in-Training who were dropped had never paid dues. We plan to investigate this group of 100 residents in more detail. For General Members, drops tend to take place at times of graduated dues increases, with a peak at year 9. The rate of dropped members who return is low, and so careful attention to retention is needed.

Our studies of member retention (at all levels) have emphasized the importance of the district branch dues structure in membership stability. We also recognize that some areas of the country (e.g., Area VI) are experiencing a "graying" of the membership, with increasing numbers being elevated to Life status, such that district branches continue to provide costly services but without the dues income base to support them. We applaud the work of the Committee on Membership and the Ad Hoc Committee on Membership and Fiscal Planning to develop a proposal for lump sum dues payments, which benefit both the Association and the membership. As of this date, 60 members have used the lump sum national dues payment mechanism. We also appreciate the leadership of the Committee on Membership in considering taking on the functions of producing a new member directory.

Although we have only the initial results of the 1992 National Resident Matching Program, these data indicate that the figures this year for psychiatry will be down considerably from last year. Family medicine and internal medicine apparently are essentially unchanged from last year, and there are increases in emergency medicine and the surgical specialties. In 1992, 526 U.S. seniors matched in psychiatry, down from a high of 745 in 1988 and compared to 641 in 1991. The initial total for U.S. and non-U.S. students matching this year was 695, compared to 786 in 1991. We also are concerned about the impact of limited funding in academic departments of psychiatry and how that affects medical student education and recruitment. Recruitment and medical student education will be a high-priority focus for our educational components this year. The APA census suggests that psychiatry residents have greater satisfaction with their field; considerably fewer residents transfer from psychiatry to training in other specialties. This information is confirmed by an AMA survey that counts psychiatrists among the most highly satisfied practitioners. Residents demonstrate interest in combined residencies and in postresidency subspecialty training. The residents themselves are bright and articulate and bring a special vitality to the Association.

Under the leadership of the American Association of Directors of Psychiatric Residency Training, APA is participating in a working conference on recruitment that was held in Chicago. We reviewed the manpower data, the results of several studies, and the recommendations from the 1980 conference on manpower and recruitment.

We also appreciate the special attention and support provided to residents through the Office of Education and, in particular, the efforts of Ms. Rosalind Keitt in coordinating activities and components addressing resident issues. This work is increasingly demanding and complex, given the growth of resident members in the Association and their increased presence in the governance structure. This year marked the fourth year of having both a Member-in-Training Trustee and Member-in-Training Trustee-Elect on the Board of Trustees, as well as significant active resident participation in the Assembly and Area councils. A component for/on young psychiatrists interacts with its companion component of young physicians in the AMA, as well as addressing the particular needs and issues related to the practice of younger psychiatrists. The retention of residents after training is quite good, and the Board of Trustees demonstrated awareness of special issues for this population by adopting a graduated dues schedule for the first years after residency training.

The Office of Education coordinates the review of nominees for the APA Dista Resident Research Award and the APA Wisniewski Young Psychiatrist Award. We continue to be impressed by the quality and sophistication of the applicants and their projects. The staff also has been developing a host of efforts aimed at medical student information and recruitment. Staff and members participated in the annual meetings of the American Medical Student Association and the National Student Medical Association this year.

The Office of Education works with district branches and other organizations to ensure that educational programs are well planned and organized. We also are meeting with district branch representatives to address the increasingly demanding requirements of the Accreditation Council for Continuing Medical Education for joint sponsorship, to ensure that there are ways for these branches to participate in the formal continuing medical education process. There has been considerable effort to develop self-learning and self-study materials, as well as formal learning opportunities. Most noteworthy has been the Psychiatric Knowledge and Skills Self-Assessment Program (PKSAP). Participants appreciate the opportunity to undertake a com-

prehensive review of their knowledge and to engage in remediation at their own pace and in the location of their choice. The program is seen as especially useful in preparation for ABPN examinations. It is anticipated that it will be part of a proposed recertification process (in the next century!).

One of our most effective initiatives in the public sector is the State/University Collaboration Project, developed by Drs. Talbott and Robinowitz. Funded by the Pew Memorial Trust, the project is co-sponsored by the National Association of State Mental Health Program Directors, the American Association of Chairmen of Departments of Psychiatry, the American Association of Directors of Psychiatric Residency Training, the American Academy of Child and Adolescent Psychiatry, and APA. Its focus is to strengthen collaborative efforts involving education, research, and recruitment and retention of psychiatrists, and the ultimate goal is a positive impact on patient care. It is an important aspect of our efforts to strengthen care in the public sector and to assist psychiatrists who work there.

In the past 2 years, under the superb staff direction of Ms. Ruth Pitlick, the State/University Collaboration Project has sponsored seven regional workshops, provided technical assistance through consultations to more than two dozen state mental health systems and academic departments of psychiatry, and presented awards to programs demonstrating model or exemplary collaboration efforts.

We urge universities and state mental health systems to request free on-site consultations on how specifically to improve their collaborative activities and effect recruitment and retention of psychiatrists in the public sector. These efforts have assisted in consciousness raising nationwide, as well as specific improvements in local function and collaboration. Plans are now under way to expand the effort to include other mental health professionals as well.

Under the leadership of Dr. Robinowitz and with direction and support by Ms. Carol Svoboda, the AIDS Education Project has provided comprehensive programs on the biopsychosocial aspects of AIDS—focusing on prevention and early intervention in addition to long-term treatment of neuropsychiatric and psychosocial aspects of HIV disorders. Conferences have focused on policy issues and emphasized participatory interaction of attendees with faculty and the active involvement of persons with AIDS and HIV disorders. The project's steering committee, under the leadership of Dr. Stuart Nichols, has served as primary faculty and has completed work on the latest edition of the *AIDS Primer* and the videotape "Dealing With AIDS" (copies of which are available on request). Much appreciation has been extended for APA leadership and educational efforts in this important area; the project has reached over 7,000 psychiatrists and other health and mental health professionals.

We have begun liaison activities with APA district branches, medical societies, mental health departments, and existing AIDS education centers to develop resource materials (including curriculum outlines, audiovisual materials, bibliographies, and reference materials); identify AIDS trainers; disseminate information; and mount educational programs. Staff has also used district branch newsletters, *Psychiatric News*, and *Hospital and Community Psychiatry* as vehicles for garnering support for project activities. Surveys were disseminated to 2,000 APA members who expressed interest in AIDS-related activities. Data are being collected to identify regional experts, researchers, educators, and clinicians. The information will be compiled for a resource directory.

The AIDS Education Project has begun collecting materials (participant training manuals, educational guides, audiovisuals) from individuals and groups across the country on the chronically mentally ill, substance abusers, women, children and adolescents, and ethnic minority populations. Staff is currently organizing, reviewing, and/or modifying this material in preparation for review by members of the steering committee, the Commission on AIDS, and selected training consultants. The project is working collaboratively with the American Psychological Association on this activity.

The January 1992 issue of the *American Journal of Psychiatry* was the first to be produced entirely with the desktop publishing system. A comparison of costs for composition (typesetting and page makeup) for the January 1991 and January 1992 issues showed a substantial decrease in expenditures. For the January 1991 issue the average cost per page for composition was \$41; for the January 1992 the average cost per page was \$9. At an average of 160 pages per issue, the *Journal*

should see composition costs reduced by about \$5,000 per issue. We will continue to investigate ways to increase efficiency and lower cost.

I would like to express my gratitude to Mr. William Baxter, our Librarian, for the consultation and assistance he has provided staff in other organizations. At this time of fiscal constraints and heavy workloads, the contributions of staff have been remarkable and highly valued. Mr. Baxter has spearheaded efforts to raise funds for the new Rare Books Room. We have received several significant donations, including a copy of the *Malleus Maleficarum*, published in 1584, during the Papacy of Innocent VIII. We also have begun to develop an on-line catalogue. The Librarian serves as staff liaison to the Ad Hoc Committee to Plan for APA's Sesquicentennial and coordinates staff and member efforts with the Committee on History and Library. We are well into the planning process for 1994; activities are under way for both the annual meeting in Philadelphia (where the founding, 50th-anniversary, and centennial meetings were held) and the Institute on Hospital and Community Psychiatry.

The American Psychiatric Foundation is continuing its organizational development, under the leadership of Dr. Elissa Benedek, Interim President, and Dr. Robinowitz, who serves as Executive Vice-President. Contributions have been made to the APA Library and Division of Public Affairs. Levels of recognition of member and corporate funding have been established. We very much appreciate the individual support provided by the Board and past Presidents; 100% of the Board members, including the resident members, have contributed. This show of support will be especially useful in our external fund-raising efforts. The foundation also is considering ways to use the APA Life Members/Fellows as a support group. I am pleased with its progress in such a brief life span and am anticipating its further support of many important Association efforts.

We are very pleased with the continued development of the Office of Information Systems. Under the leadership of Dr. William More, we have implemented innovative approaches to information services for our members. Our ability to communicate, as well as collect and retrieve information, has expanded immensely. We are very proud of the ongoing routine work of the Association regarding member communication, dues billing, accounting, and financing. Dr. More, who is nationally recognized as a medical statistician, has been an excellent resource in our information generation and data analysis. He bridges the enormously complicated demands of the financial and other aspects of our needs in a creative and supportive manner. We believe that in the future communication and information will be an increasingly important base of our function.

This year marked the 10th anniversary of the American Psychiatric Press, Inc. (APPI). In its first decade, APPI has had spectacular growth, providing outstanding scientific information to the profession and the public, and has become the premier publisher of psychiatric books. APPI has recently initiated publication of five journals, covering the important topics of education, addictions, neuropsychiatry, psychosomatic medicine, and psychotherapy. Congratulations are due Dr. Carol Nadelson, Editor-in-Chief, Mr. Ronald McMillen, General Manager, and staff for their outstanding achievements. APPI has fulfilled three important functions: bringing the best authors and writing to print, providing the best information on topics important for the profession and the public, and generating income to support APA priority activities.

I am most gratified by the creative leadership and energy shown by past President Dr. Carol Nadelson as APPI's Editor-in-Chief. In the past year she has been extremely active not only in broadening and strengthening the ongoing work of APPI but also in outreach to develop strong working relationships with potential authors in this country and abroad. The APPI Editorial Board has been broadened to include experts in a variety of clinical areas. APPI's staff work in expanding our foreign markets has resulted in new professional and business alliances plus greater opportunities. In its 10 years of existence, APPI has become well recognized and highly regarded in the publishing industry. Not only does it have a competitive edge in psychiatric publications, as evidenced by the content of book reviews and by sales volume, but its products also provide an opportunity for scientific education and negation of some of the stereotypes about psychiatry and psychiatric patients.

As a result of a copyright exchange between APA and WHO, APPI will be a major distributor of *ICD-10* in the United States. The "Blue

Book," *ICD-10*, chapter V, on mental and behavioral disorders, will make its first appearance in the United States at the APA annual meeting. The complete *ICD-10* will follow shortly. As a Publishing Partner in Health with WHO, APPI will make available other WHO publications related to psychiatry.

As part of our planning for the World Psychiatric Association meeting in Rio de Janeiro, I am pleased that Drs. Nadelson and Jorge Costa e Silva have agreed to edit an international update, to be published by APPI. This represents a good blend of our interest in international and multicultural topics with the expertise provided by APPI.

Deserving of special recognition are the sustained, remarkably high-level contributions of Mr. Joel Klein. He and his colleagues have done much to support our efforts. We were saddened at the dissolution of the law firm Onek, Klein, and Farr last summer but relieved to retain Mr. Klein's expertise on the Commission on Judicial Action. I will touch on his work on professional liability at a later point. Mr. Klein has been a valued friend as well as counselor through a number of difficult and thorny decision points. Since last summer we have worked primarily with Ms. JoAnn Macbeth, formerly of Onek, Klein, and Farr, now with Crowell and Moring, a full-service law firm. She and her colleagues have been extraordinarily helpful in a wide range of activities related to our business and policy efforts, especially in the work with our ethics procedures. Last year Dr. Hartmann appointed a committee of two, Drs. Benedek and McIntyre, to review our legal needs and make recommendations for the future. In March the Board adopted their recommendation to name Ms. Macbeth as APA legal counsel, continuing our appellate work with Mr. Klein. APA will be well served.

For our insurance program to be successful and meet members' needs, we must constantly deal with the interface and conflict between functioning as a member organization and as a business. While we have to be sensitive to all of the issues and problems practitioners have in dealing with threatened liability, we also have to base the program on a sound fiscal footing and avoid adverse selection. We do offer the best program for meeting members' needs and have more provisions for member choice and control in case settlement. Unlike most commercial carriers, we do not cancel coverage on the basis of suits or claims made. Further, "profit" goes back to the membership in the form of lower premiums, rather than to stockholders. We also are offering on a pilot basis a claims-made policy that may be useful for younger members just beginning practice or those who plan on a stable practice for some time.

Ms. Elizabeth Thomas and Ms. Dara Schumaier developed a strong working relationship with Professional Risk Management Services, Inc. (PRMS) and have been extraordinarily helpful in addressing and solving problems of communication and information. Through their efforts and those of Mr. Rich Feeley, our staff insurance and financial consultant, the number and intensity of insurance-related complaints have fallen considerably.

We have been fortunate to have such effective staff support for our insurance program. Ms. Macbeth, Mr. Klein, and Dr. Robinowitz have devoted much energy to its good functioning and success. Additionally, Dr. Alan Levenson has provided extraordinary leadership, time, and energy to ensure the best possible program and outcome. We also appreciate the contributions made by the many members involved in the committees addressing insurance issues. Their efforts have been vital to our members' practices.

Business ventures demand both substantive knowledge of issues affecting our members and their practices and a sound fiscal structure. Dealing with tight budgets, the recession, and the leveling off of income while ensuring prudent planning for the future financial strength of the Association has been a monumental effort, demanding considerable member and staff coordination and proactive planning.

This year we have focused extensively on budget and financing. Over the past decade we increasingly used outside funds (nondues income) to support new and high-priority projects. The termination of our Quality Assurance Program brought with it not only the costs of termination but also a loss of outside income. This is reflected in the lack of funds for new projects and also brings the realization that increased funding is needed just to maintain the inflationary growth of ongoing programs. In response to members' concerns, dues for 1992, which represent some 40% of the operating budget, were held to an increase paralleling inflation. The recession has had an effect on

both income (e.g., from advertising sales) and the costs of doing business (e.g., travel, postage). It also is felt in the increased number of members requesting dues relief.

Consequently, the 1992 budget is not able to maintain 1991 programs at the level of inflation or to fund and initiate new programs. We are pleased that we ended 1991 with a balanced budget and a very small surplus. Extremely careful monitoring of expenditures and attention to generation of funds and use of resources was needed to effect this outcome. In particular, the *American Journal of Psychiatry*, the annual meeting, and APPI were noteworthy sources of income. To continue in this direction will demand care on the part of staff and members in monitoring expenses and generating income.

We have improved cost-effectiveness through integration and consolidation of efforts and careful review of priorities and expenditures. With the assistance of Mr. Feeley, we developed a model to analyze monthly expenditures according to seasonal variation, since our expenses do not occur at a regular monthly rate but, rather, in predictable response to events on the Association's calendar each year. We continue to monitor departmental expenditures closely to ensure compliance with this year's budget and fiscal state. Positions are almost always frozen when current staff depart, supply and equipment purchases are curtailed, and travel also is severely limited. The new travel contract was designed to provide savings, as is our increased use of desktop publishing. Morale is an issue, as we curtail some resources without limiting activities. At the same time, we want to avoid layoffs. Staff and members alike will feel the pinch as we attempt to streamline efforts further, and I recognize that the leadership will continue to be approached by many members requesting support for programs and activities they consider of highest priority. The next few years will be a time of careful priority setting, and the results of our fiscal actions will be vital to the long-term health and function of the Association. We have been most fortunate to have Dr. Donald Scherl as chairperson of the Budget Committee. His wisdom and careful attention to long-term, as well as immediate, issues is remarkable. He and staff have worked closely with APA Treasurer Dr. Mary Jane England and with Board and Assembly leaders on financial planning and implementation, ensuring income for the Association and regulating expenses. I especially appreciate the efforts of Drs. Robinowitz and White, Comptroller Mr. Robert Milanicz, and Mr. Feeley in what represents a longer-term strategic financial planning endeavor. They have done an excellent job not only in planning and execution but also in dealing with the many individual needs generated by fiscal restraints.

As part of the 1993 Presidential theme and directions set by President-Elect English, we have had several meetings to address issues related to access to, and delivery of, services in the public sector. I have had some very gratifying contacts with Dr. Richard Surles, Commissioner of the New York State Office of Mental Health. He has expressed his strong support for the role of psychiatry in public mental health settings. Dr. English is planning a small invitational working conference to begin a process to address these topics and to consider

issues of professional values, development, and function, as well as patient care, in the context of economic constraints and environmental forces that will be at play in the coming decade. We have obtained financial support for the initial working conference from NIMH and from Dr. Alexander Gralnick, Psychiatrist-in-Chief at High Point Hospital in Port Chester, N.Y.

No report would be complete without some comments about staff in my office, whose work has been exemplary. Mr. David McClanahan has contributed strongly to the day-to-day smooth functioning of my office. Ms. Katherine Chambless has been a marvelous addition to the team. Ms. Sandy Hazen has been invaluable in so many areas, including production of this report. We were delighted at the return of Ms. Emma Wilkins to our staff; her willingness to assist whenever and wherever needed is a model for us all. Dr. Robinowitz also has been pivotal in this integrative effort, which, in my judgment, shows APA at its working best. Further, Dr. Robinowitz has consistently taken on increasing responsibilities in all areas of Association functioning and has performed magnificently. As far as I am concerned, our working partnership in the day-to-day and long-range management is excellent.

Of vital importance is the presence of a largely behind-the-scenes staff member who takes major responsibility for making it all happen. Ms. Carol Davis oversees the functioning of my office and all of its related activities, while at the same time maintaining major staff support responsibility for the demanding work of the Ethics Committee, the Ethics Appeals Board, and our involvement with the AMA. She has a special ability to develop and implement planning processes and is an extraordinarily knowledgeable and sensitive resource. The nature of her work is such that she rarely receives public attention or recognition, yet her contributions are invaluable and she has won the trust and respect of us all.

Comments about "the best in APA" are a good link to my belief that we have been extremely fortunate in our choice of leaders. Our President, Dr. Lawrence Hartmann, has been outstanding; his knowledge, vision, concern, and effectiveness have had a major impact on our functions and our future. Our Speaker, Dr. Thomas Pfahler, also deserves special recognition. His sensitivity to and knowledge of Assembly moods, directions, and needs and his remarkable ability to deal with administrative issues while working closely with members and staff have made him especially effective for the Assembly and the Association. It has been a privilege to work with all of our members this year toward a stronger and more effective APA, and I anticipate an excellent alliance with our incoming President, Dr. Joseph English, and with the next Speaker, Dr. Ronald Shellow, and all the other APA members who serve the Association and the field so ably.

Extensive reports on the individual staff departments are available from the Central Office. They attest to the diversity, enormity, and complexity of staff efforts and demonstrate our commitment to strengthening the field and supporting our members and the patients whom they serve. It is a privilege and pleasure to be Medical Director of such a strong and vital organization.

Report of the Speaker

G. Thomas Pfaehler, M.D.

The theme of my Speaker-Elect's report was evolution: the evolution of issues, the evolution of the Assembly, and personal evolution. Diverse issues continue to command the attention of the Assembly. These issues continue to occupy the efforts and resources of APA:

- *Professional liability insurance.* This program has been recently tested in the glare of national media.
- *Quality assurance and APA.* Quality assurance has drifted further from the control of APA, and quality improvement has only appeared on the horizon.
- *American Psychiatric Foundation.* APA must decide whether to commit to outside fund raising under the coordination of its affiliated foundation.
- *Practice guidelines.* Two major guidelines, on eating disorders and major depression, are nearing final approval and publication.
- *CPT-IV.* Confusion still reigns as different geographic areas and fiscal intermediaries provide different rules and interpretations for *Physicians' Current Procedural Terminology*, 4th edition.
- *Managed care.* 1991 has seen progress in confronting firms using abusive and inappropriate methods. *Utilization Management—A Handbook for Psychiatrists* ("Survival Manual") is a great success.
- *DSM-IV.* The DSM-IV, *Work in Progress: Options Book* has been available through the year to provide insight into the process of developing the latest nosological scheme.
- *Recertification.* Continuing to bear down on the membership with time-limited certification just 2 years away, recertification is a pressing issue.
- *Resource-based relative value scale.* APA has been successful at limiting the degree to which the federal government has fallen short of the intent of the law in implementing this system.
- *Active service of minority and underserved populations.* APA continues its struggle to maintain credibility as the umbrella organization for these groups amidst an increasingly pluralistic society with rapidly growing minority groups.
- *Subspecialization.* With the establishment of added qualifications for the most obvious of clinical populations, APA now faces the challenge of possibly saying "no" to petitioners.

Now, with these issues in mind at the end of my term, I wish to accomplish two tasks: first, I wish to state the challenge I see facing APA, and second, I wish to take the opportunity to acknowledge those who have been important to me during this year.

CHALLENGE

Given the breadth and complexity of the issues facing us, we must seriously question whether APA can confront all of them effectively. If all cannot be confronted, a system of priorities is essential. We must make hard decisions regarding the expenditure of resources, the allocation and size of staff, and the satisfaction of some people, occasionally at the expense of others. To be effective in essential areas may require small membership attrition and loss as APA faces, with other large organizations in our society, the necessity of modifying the ideal of being all things to all members.

APA no longer exists in a world that automatically grants favored positions to physicians and other professionals. Increasingly we must earn, and re-earn, our recognition and benefits. We will be increasingly scrutinized in sometimes painful ways, as we were in the "Frontline" program on PBS. The impact on us all of professional misfortune and poor judgment on the part of a few of our prominent members, as demonstrated in recent events, is hurtful and diminishing to our reputation.

The practice of medicine has been regarded by regulators as a busi-

ness for two decades. We must continually tread carefully to avoid damaging our unity by exclusive attempts to preserve our professional identity.

- Which of the issues previously identified deserve the highest priority?
- Will we always be perceptive and courageous enough to take the professional "high road" when attacked or when embarrassed and sullied by the behavior of a few of our own?
- Can we avoid unnecessary and resource-exhausting battles with competing professional groups and government-sized regulators of our practice that could cause us to lose the war of professional survival?
- Can we conceptualize ourselves and what we do responsibly and flexibly enough to permit recognition of the need for change and evolution within the society around us?
- Can we recognize the fact that we and other professionals, such as college professors and public servants, are no longer the masters of the roles we fulfill in society but are increasingly having our roles defined by others—frequently those others who either consume or pay for our services and demand value and quality outcomes?

My year as Speaker has shown me that all of these questions are constantly appearing in the work facing the Assembly. The year has built my confidence that the Assembly can, and does, confront the issues when they arise. For example, it confronts the conflict between those who believe APA should control what roles are acceptable for its members through incentives and disincentives and those who believe we should cooperate with redefinition of our roles while working to exemplify the best of our professional contributions. It confronts the conflict between the need to finance the operations of APA while at the same time requesting members to provide additional personal and financial resources to support educational and special endeavors. The strength to make our negotiations credible, and our challenges of others formidable, requires such resources.

ACKNOWLEDGMENTS

In closing my year I must, as have all Speakers before me, recognize that I am a part of a continuum. I am able to serve the Assembly ably only insofar as I can recognize and use the support and knowledge of those around me. Past Speakers Dr. Edward Hanin, Dr. John McIntyre, and Dr. Gerald Flamm have been available and supportive, often giving me time from their own busy and advancing careers. The Speaker-Elect, Dr. Ronald Shellow, has been available and has provided valuable counsel. His eagerness to assume his own place in the continuum becomes him. It will be a pleasure to pass the gavel to him.

Dr. Lawrence Hartmann has been an easy and steady influence in subtle ways throughout the year. I have discovered in him a source of support of which even he may be unaware.

Mr. Michael Murphy, Ms. Jeanne Robb, Ms. Lea Mesner, and Ms. Elisabeth Fitzhugh from the Office to Coordinate the Board and Assembly are indispensable. This report is perhaps the only thing that does not appear in the literary style of one or another of these valued people. They are our memories, our planners, and, often enough, our encouragement. Michael Murphy will be missed but is also to be congratulated for his promotion.

Finally, the superb staff under the guidance and direction of Dr. Melvin Sabshin continues to serve APA well in private and in public arenas. Mr. Jay Cutler and Mr. John Blamphin, particularly, are willing to advise, to challenge, and sometimes to risk in the service of advancing the values of psychiatry.

I thank, mostly, the members of the Assembly who elected me and provided me with this opportunity to serve. I hope that the personal evolution of which I spoke in May of 1991 has been as evident to them as it has to me.

Last, I recognize my family, who tolerated delays in tasks resulting from my absence, provided rides to the airport (and sometimes home from the airport), and generally encouraged and advised me during the year. Their support was, and is, essential.

Report of the Speaker-Elect

Ronald A. Shellow, M.D.

The Speaker-Elect is expected to report to the Association at the annual meeting. Two factors color my report—pleasure at APA's return to its important goals and altered perceptions resulting from a year in this office.

First, after a period of increased focus on protecting guild interests of members, APA has returned to emphasizing its stated goals: to promote learning and exchange of knowledge, to share appropriate standards and ethics within our specialty, and to be advocates for our patients locally, nationally, and internationally.

The second factor influencing me was my role as Speaker-Elect, assisting the Speaker and cochairing the Joint Reference Committee. Additionally, I continue with committee responsibilities, the Section Council on Psychiatry to the AMA, and district branch work. These activities, which compelled me to be away from my office 20% to 30% of last year, have made a great difference in my solo private practice. Local physicians no longer refer patients to me, I see no hospital patients, and I must more carefully select new psychotherapy patients. I am not available to work in any managed care settings aside from meeting demands of the insurance carriers for some of my outpatients. To fill the gap, I have increased consultations, evaluations, and forensic practice. The combination of these changes has given me a different perspective on organized psychiatry, which leads to the following thoughts. By accentuating our professionalism, the Association is taking steps that help psychiatry better serve our patients' welfare. I am proud of this direction and hope colleagues share my pride.

One of the outstanding contributions of APA, not only to our patients but to all of medicine, has been more accurate diagnosis of psychiatric disorders. To further aid in this critical task, we are in the midst of producing *DSM-IV*. Recognizing its importance, the Assembly has provided substantial input for this project. Each member received, and many commented on, *DSM-IV, Work in Progress: Options Book*. We look forward to the timely publication of *DSM-IV*.

I am personally more involved in production of practice guidelines. T. Byram Karasu and the Task Force on Treatments of Psychiatric Disorders gave our specialty a huge push forward by publishing the four-volume *Treatments of Psychiatric Disorders* several years ago. Building on this start and evolving from recommendations originating in the Assembly, through a steering committee now chaired by John McIntyre, the first guideline is almost ready for publication. The second guideline is near completion, and the next two should be ready later this year. This process can only help improve standards of psychiatric care for people suffering from mental disorders. Other probable benefits of the guidelines include improving relations with other specialties of medicine, easing the burden of professional liability, and assisting in work with parties involved in financing health care. The guidelines project deserves increased support, both for initial publication and frequent revisions. Expanding knowledge in psychiatry demands this.

Our focus on access to health care for psychiatric patients highlights another way in which APA tries to help these patients. While psychiatry is really a small player in the arena of comprehensive health care, too many of our patients have no access to the system

of insured care because of insufficient money, preexisting illnesses that make them "indentured servants" to employers who carry their present insurance, unrealistic present benefits, or managed care agencies that so interfere with the system as to negate their psychiatric benefits. Small player or not, on behalf of our patients APA must continue to work diligently with government, industry, patient advocacy groups, our members, and other interested parties. We continue to educate ourselves about all systems purporting to improve access. Our primary focus, however, should be to attempt in every reasonable way to provide adequate, preferably nondiscriminatory, third-party benefits to those patients. The Assembly has advanced this position to the more executive components of APA: Board of Trustees, Joint Reference Committee, Joint Commissions on Government Relations and Public Affairs, Committee on Universal Access to Health Care, and staff. Emphasis on psychoanalytic concepts in the past may have slanted the profession too far in one direction. Spectacular achievements in biological psychiatry now may be pushing us too far the other way. Prompted in part by Lawrence Hartmann's Presidential theme emphasizing a biopsychosocial perspective, the Assembly asked the Scientific Program Committee to ensure that members have more opportunities to maintain and improve skills in psychotherapy. Additionally, the Assembly has urged caution in isolating "biological" psychiatric illnesses from those which, at this time, are still labeled "purely functional." We must be careful not to abandon any patients who could benefit from psychiatric help.

APA continues to actively promote the welfare of psychiatric patients by trying to improve standards for their care. As part of this effort, we oppose inappropriate extension to nonphysicians of the privilege of prescribing medication or admitting and treating patients in hospitals without supervision. Some psychologists have called this a "turf issue." They are wrong. Instead, it is an issue of proper care for sick human beings. Nonphysicians who are less qualified simply cannot competently care for patients, and, in fact, psychiatrists themselves should seek additional training and education. On behalf of our patients we must try to ensure that utilization management does not interfere with delivery of high-quality, efficient psychiatric care. We must continue to be vigorous in promoting high standards and combating excesses of utilization managers, especially now that the Assembly has given the Board a rational set of prioritized approaches.

APA is the most vigorous of all medical and specialty organizations in promoting high ethical standards of professional conduct. We should be proud of our record and diligent in trying to improve that record. We should also seek methods of ensuring that our public image truly reflects the assertiveness of our work in this regard.

Further, in a time of serious fiscal difficulty APA should continue attempts to preserve funding for research into mental disorders.

APA is one of the most representative medical organizations. In part, this responsiveness to its membership is a product of its governance structure. The Assembly continues to be an important and effective component of that governance. I have been particularly fortunate this year to have been able to work with the Speaker, G. Thomas Pfahler, a man of extraordinary administrative and organizational

skills combined with great patience and creativity. As Speaker-Elect I have also worked closely with President-Elect Joseph English. Joe has outstanding concentration and an innovative, outward-looking vision of our organization. He has been a superb chairperson of the Joint Reference Committee. The three immediate past Speakers of the Assembly—Edward Hanin, Gerald Flamm, and John McIntyre—and Parliamentarian Frederick Gottlieb have been of great help to me with advice, counsel, and hard work whenever asked. Medical Director Melvin Sabshin has, with grace and style, in this time of financial constraint, maintained important aspects of APA's goals for our mem-

bers and profession. The staff of the Office to Coordinate the Board and Assembly, led by Jeanne Robb and including Michael Murphy, Lea Mesner, and Elisabeth Fitzhugh, have been superb in willingly supporting and carrying forward the institutional memory and day-to-day functions of the Assembly, district branches, and other components of the governance structure. Corky Hart, providing staff assistance to the Joint Reference Committee, has played an important role in coordinating Assembly issues in councils and other components. Members of the Assembly of District Branches have given their time, energy, and hard work for all the membership. I thank them all.

Report of the Committee on Constitution and Bylaws

Henry Payson, M.D., Chairperson

The Committee on Constitution and Bylaws this year accomplished its work by mail ballot, and I am indebted to the members of the committee for completing its business so expeditiously. They include Drs. William Spiegel, Richard Thurrell, Walter Shervington, Naomi Goldstein, Alexandra Symonds, and Lee Park, Assembly liaison. The committee was assisted by Ms. Carol Lehmann of staff.

The committee was asked by the Medical Director to review the part of chapter 8.5 (the Bylaw that outlines procedures for referenda) that reads, "For a referendum to pass, at least 40 percent of the total number of members eligible to vote must vote and at least one-third of the total number of members eligible to vote must vote in favor." Given the current wording, it is possible, albeit unlikely, for a referendum to pass without a majority vote. The committee prepared an amendment which stipulates that a majority vote is needed for a referendum to pass.

At its March 21–22, 1992, meeting, the Board of Trustees approved the amendment for reading to the membership at the 1992 annual business meeting and for inclusion in the 1993 ballot. The text of the amendment follows.

At its March meeting the Board also asked the committee to approve an amendment to chapter 10.1 that will allow the name of a member who resigns before an ethics complaint is filed to be reported to the membership and to the National Practitioner Data Bank, if the complaint is filed within 90 days after the member submits the resignation. The committee approved this amendment; the text follows.

PROPOSED AMENDMENTS TO THE CONSTITUTION AND BYLAWS

The following amendments were approved by the Board of Trustees in March and April 1992 for reading to the membership at the 1992 annual meeting. The amendments will be disseminated to the membership not later than Jan. 1, 1993, and will appear on the 1993 ballot. In the text that follows, bold underscoring indicates additions.

Chapter Eight. Privileges and Responsibilities

5. The voting membership may initiate referenda or change an action of the Board by the following procedure: A petition signed by at least 500 voting members shall be submitted to the Secretary by November 15 to be voted on in the mail ballot in the following year. A statement from the petitioners setting forth the reasons for the action, following consultation with the President, Speaker, Medical Director, and legal counsel (including fiscal advice), and a statement from the Board shall accompany the ballot. For a referendum to pass, at least 40% of the total number of members eligible to vote must vote and at least one-third of the total number of members eligible to vote must vote in favor. **In addition, it requires a majority vote.** A referendum overturning an action of the Board shall be binding, except that the action may be reinstated by a two-thirds affirmative vote of the members of the Board eligible to vote and by a two-thirds affirmative vote of the members of the Assembly Executive Committee eligible to vote. A Board action to reinstate may be taken only at a regularly scheduled meeting occurring no sooner than one month after the meeting at which the referendum was certified. Certified referenda other than those overturning an action of the Board must be acted on by the Board with all deliberate speed.

Chapter Ten. Ethics Complaints and Disciplinary Procedures

1. Complaints charging members of the Association with unethical behavior or practices shall be investigated, processed, and resolved in accordance with procedures approved by the Assembly and the Board. The name of a member who resigns during an ethics investigation may be reported to the membership. **The name of a member against whom an ethics complaint is filed within 90 days after the member submits a resignation may be reported to the membership and to the National Practitioner Data Bank.**

Report of the Committee on Membership

Aron S. Wolf, M.D., Chairperson

The Committee on Membership met Nov. 5–8, 1991, in Washington, D.C. Present were Drs. Aron S. Wolf (chairperson), Jack W. Bonner III, Fernando J. Cabrera, Siobhan Coomaraswamy, Lois B. Fuller, Rodrigo A. Munoz, A. Granville Tolley, and Michael J. Vergare (consultant); Ms. Elizabeth Thomas, Director, Office of Membership; and Office of Membership staff. Guests present were Dr. Melvin Sabshin, Medical Director; Dr. Carolyn B. Robinowitz, Senior Deputy Medical Director; Dr. Harold A. Pincus, Deputy Medical Director; Dr. William More, Director, Office of Information Systems; Mr. Thomas Dial, Assistant Director for Research Studies; and Dr. James R. Rundell, President of the Society of American Military Psychiatrists.

The committee held a joint meeting with the Assembly Committee on Membership Recruitment and Participation on Friday, Nov. 8, 1991.

Certain information contained in this report has been updated since the November meeting.

MEMBERSHIP DEVELOPMENT

The total membership as of April 1, 1992, was 37,512, which reflects a net gain of 361 in 1991. The net gain for 1991 is below the net gain of 710 for 1990, in part because of the stable numbers of medical students entering psychiatric residencies, which has resulted in fewer new members, and in part because of increased economic pressures on members, who may find membership dues less affordable than in the past.

1991 was the first year in which annual membership termination for nonpayment of APA dues took place in June rather than December. Losses due to membership termination for nonpayment of APA national dues were not as severe as anticipated but were in line with the organization's experience in previous years. Losses were kept to a minimum largely because of extensive personalized correspondence between the Office of Membership and members facing termination.

The distribution of members among the membership classes from 1988 to 1992 can be seen in table 1. A summary of percentage changes in membership by Area from 1986 through December 1991 is given in table 2. Five of the seven Areas showed net losses for 1991. The downward trend for 1990 and 1991 requires serious consideration by everyone in the APA leadership.

It is important to note that table 2 reflects not only annual terminations but also the removal of Medical Student Members from Area and district branch membership (as of July 1, 1991, medical students were enrolled as APA members only). As of April 1992, Medical Student Members comprise 2.0% of the membership overall. The new one-time-only \$25 fee seems to have been well received; during 1991 medical student enrollments increased slightly in September and October over previous months.

As of April 1, 1992, the 5,823 Members-in-Training plus the 745 Medical Student Members represent a substantial 17.5% of the total membership. Members-in-Training continue to be the greatest source of new General Members. It is believed that close to 80% of all psychiatric residents are members, and increased emphasis on recruiting the remainder is a priority. The proportion that had been used previously was 90%; an appraisal of the advancement data accounts for the difference. The number of new members who are enrolled as General Members is still decreasing, while the proportion of those who become General Members by advancement has grown steadily. Table 3 shows General Member enrollment versus advancement from Member-in-Training for the past 8 years.

In October 1991 the Office of Membership sent 2,277 letters to all Members-in-Training who had held that status for 5 or more years, asking them to initiate advancement of their membership or notify the office of any continued training they have undertaken. Traditionally, the district branches have been provided with rosters of their members who may need to advance so that the branches can contact

these members. The Office of Membership hopes that by contacting members directly advancements can be accelerated and some of the paperwork burden at the district branch level can be relieved (some district branches do not have staff but rely on members to handle membership transactions and paperwork).

In October 1991 each member whose mailing address fell outside the jurisdiction of the district branch to which he or she belonged was mailed a letter asking the member to initiate the transfer process. After that initial mailing, on a monthly basis the Office of Membership began sending letters to members whose changes of address indicated a need to transfer district branch affiliation.

Table 4 shows membership transactions for 1991, and table 5 summarizes the transactions for 1982–1991. Membership reinstatements were up in 1991; more members were reinstated during 1991 than during 1990 (56 Members-in-Training and 170 General Members were reinstated in 1991, compared to 36 and 123, respectively, in 1990). This may be due in part to the dues amnesty that had been in effect for 1990 and 1991 (members owing more than 2 years' dues before 1988 paid only the more distal year's dues to be reinstated).

In addition to a successful reinstatement campaign, during 1991 the Office of Membership contacted 91 new diplomates of the American Board of Psychiatry and Neurology (ABPN) who had never been APA members about joining APA. Another recruitment project involved contacting over 1,000 female psychiatrists who had not previously belonged to APA; of 1,045 who received letters and applications, 121 became members of APA and their local societies (91 as Members-in-Training and 30 as General Members). This represents 11.6% of those contacted, which is a very high return for this type of recruitment effort (2%–3% is the average return).

The schedule for APA national dues was revised for 1992. Dues for General Members now increase more gradually, from 30% of full dues during the first year of General Membership to full dues in the 8th year of General Membership.

During 1991, 370 members resigned from APA, 526 members were dropped for nonpayment of dues, 174 members were dropped by their district branches (and therefore also by APA), and 152 Medical Student Members were dropped because their membership had expired by virtue of their graduation from medical school.

There have been staff changes in the Office of Membership since the committee's last meeting. Ms. Elizabeth Thomas was promoted to Director after former Director Marta De Lalla, Ph.D., resigned to return to Argentina. Also, Ms. Dara Schumaier, who was the Coordinator for Recruitment/Retention, was promoted to Special Assistant to the Senior Deputy Medical Director (Dr. Carolyn Robinowitz). Mr. Michael Murphy was promoted from the Office to Coordinate the Board and Assembly to Assistant Director of the Office of Membership, and Ms. Susan Kuper was promoted from the Office of Psychiatric Services to Coordinator for Recruitment/Retention in the Office of Membership.

FELLOWSHIP

The Committee on Membership received 228 nominations submitted by 58 district branches for elevation of members to Fellowship. The five requests for waivers of the 2-year waiting period or the 8-year General Member requirement were all denied, and thus the committee reviewed the remaining 223 nominations. The approval rate was 81.6%: 182 candidates' nominations were approved, and 41 were deferred. The committee commends the district branches for their fine work in ensuring that the nomination materials submitted were complete, thus ensuring a fair evaluation of the candidates.

The issue of Fellowship denial at the branch level was discussed in depth by both membership committees. This issue arose from a review of one member's concern that his nomination had been blocked by

TABLE 1. Members in Each Class, 1988–1992

1990	1,408	182	1,226	87
1991	1,080	180	900	83

the district branch, and it was revealed that no specific appeal mechanism appears to be in place. Procedural and legal issues will be referred to appropriate staff for clarification, and the committees will discuss this matter again at their joint meeting in May 1992.

The committees refined and clarified the guidelines for election to Fellowship to be used from 1992 onward. One of the purposes was to deemphasize certain characteristics, such as board certification, while encouraging public sector service (as requested by the Consortium of Chairpersons of APA Public Psychiatry Components) and socially responsible medical and mental health activities that are unremunerated.

Finally, the committee continued discussions regarding ethics and revocation of Fellowship of members who are under suspension. Committee members continued to have unanswered questions about how suspension relates to the honor of Fellowship. The committee will continue its dialogue with the Ethics Committee and will ask for further clarification from that committee about the relationship between suspension and Fellowship. The central issues are whether Fellowship is primarily a member class, a one-and-all-time honor, or an acknowledgment of both past and present honorary status within APA.

SELECTED MEMBERSHIP ISSUES

Reduced Dues

A request for reduced dues for academic psychiatrists was reviewed by the Committee on Membership. The committee believes that the

current dues relief options available to members adequately meet the needs of those who are unable to meet their dues obligations; it was also noted that several dues billings are sent throughout the year, enabling members to make partial payments. The committee also discussed correspondence from residents regarding the level of district branch dues. The committee strongly recommends that the district branches exercise considerable restraint in setting dues for residents.

Dues Late Fee or Discount

The committee continued its review of information, including an opinion from legal counsel, about the use of late fees or discounts connected to dues payments. The committee will solicit further information exploring the feasibility of offering a prompt-payment discount (including a cost-benefit study and questions to district branches who use discounts and/or late fees about their experiences), keeping in mind the large number of members who already pay their dues promptly. It was felt that charging a late fee would be counterproductive because it may be viewed as punitive.

Recruitment for Western Canada District Branch

The committee reviewed correspondence between the President of the Western Canada District Branch and the Office of Membership addressing strategies for recruiting (and retaining) members for this district branch. The committee suggested that the recruitment problems may be geographically based. It believes that the Western Canada District Branch might investigate the benefits of subdividing, forming

a new "prairie" district branch consisting of Manitoba, Alberta, and Saskatchewan. A first step in this process might be for the Western Canada District Branch to identify members in its three provinces east of the Rockies who might be possible leaders (should the branch subdivide). The outcome of this discussion was shared with the president of the Western Canada District Branch.

Annual Statement From Members

A request was received from a district branch asking if the APA Bylaws prohibit asking a member if she or he has been convicted of any ethical violation, has been found liable in a malpractice suit, or has had hospital privileges revoked or rescinded. APA legal counsel was asked for an opinion on requesting members to sign an annual statement on these matters. Although neither counsel nor the committee found any problem with the branch's soliciting this information from its members, the committee felt strongly that a number of questions raised by legal counsel should be carefully considered by the district branch before it implements such a procedure. The branch did not specify how it intends to use the information. Counsel stated in the opinion that its use may well contravene—at least implicitly—provisions of both the Bylaws and the "Operations Manual of the Board of Trustees."

Dual Membership Requirement

The committee reviewed correspondence from several members who objected to belonging to their local district branches. The committee reviews similar correspondence each year; it reiterates the value and importance of maintaining the dual membership requirement and will not grant exceptions to this requirement.

Osteopathic Physicians

At the request of both membership committees, the Committee on Graduate Education was asked to review the accreditation standard of the American Osteopathic Association as an initial step in determining eligibility for General Membership (General Members must have completed a psychiatry residency training program approved by the Accreditation Council for Graduate Medical Education [ACGME]). The Committee on Graduate Education foresaw a conflict in reviewing and sanctioning a second accreditation track and was reluctant to take a position on this issue. The membership committees reached the conclusion that at this time it is not possible to include formally in the APA membership psychiatrists with osteopathic psychiatry residency training. Both committees suggested that district branches interested in including osteopathically trained colleagues in continuing medical education and other branch activities develop local-level invitational mechanisms to maintain contact with them.

Lump-Sum Dues

The option of paying APA national dues in a lump sum currently is being offered to members who are 40 years old or older. Although this option is new, 62 such payments had been received as of April 1992. In response to the interest of a member younger than 40, APA's financial consultant will be asked to calculate the appropriate lump-sum amount for members aged 35–39 years.

Annual Meeting Workshop

The Scientific Program Committee accepted the Committee on Membership's proposal to conduct a workshop at the 1992 annual meeting in Washington, D.C. The focus of the workshop, an interactive meeting, will be on issues involving both membership recruitment and membership retention. District branch officers, staff, and chairpersons of membership-related committees are encouraged to attend and will be notified specifically of this workshop.

Dues Relief Criteria

A subcommittee of the Committee on Membership (Drs. Fuller and Coomaraswamy) will be redrafting criteria for use by the committee and the district branches in acting on requests for dues relief. Both the Constitutional and Assembly membership committees discussed at length the practice of some district branches of requiring financial statements from members who request dues relief. There were strong sentiments in both committees that this requirement poses confidentiality problems and that district branches should ask only for relevant information pertaining directly to the request. A letter will be sent by the Committee on Membership to all branches, highlighting this concern.

Committee on Young Psychiatrists

The Committee on Membership has been working with the Committee on Young Psychiatrists, which has requested longitudinal studies and a study of issues related to the retention of young psychiatrists (a "young psychiatrist" is under 40 years of age and/or has completed psychiatry residency training within the past 5 years). After meetings between representatives of both membership committees and staff, it appears that compromises have been reached which fulfill the needs of the Committee on Young Psychiatrists, taking into account current budgetary limitations. The Committee on Young Psychiatrists originally had asked that the Office of Membership undertake studies which could not be performed with current staff levels; the Committee on Young Psychiatrists is considering working with information that the Office of Membership can provide easily on a periodic basis.

Foreign Psychiatrists Who Receive Specialized Training in the United States or Canada

The Committee on Membership agreed that foreign-trained psychiatrists who come to the United States or Canada for a specified period of time to receive specialized training in psychiatry, who are not eligible for either Member-in-Training status or General Member status, shall be considered special applicants to be presented to the Committee on Membership for consideration as nonvoting, dues-exempt Corresponding Members, as they would be if they applied from their home countries. The local district branches would be encouraged to include these Corresponding Members in branch activities.

Ethnicity

The Committee on Membership has been discussing how race/ethnicity information is collected on the General Membership application form. The committee decided to return to a simplified race/ethnicity question that has single categories for Hispanic and Asian designations.

6-Year Limit for Members-in-Training

A Member-in-Training asked the Committee on Membership to consider changing the 6-year Constitutional time limit for Member-in-Training status. She expressed the concern that women are not always able to complete training within 6 years, especially if they have family obligations. The committee felt that the current system (including the process for granting waivers or Inactive status) allows flexibility and can meet demands of Members-in-Training whose training takes longer than 6 years.

International Membership

The Committee on Membership, at the request of the Joint Reference Committee (upon request by the Council on International Affairs), briefly discussed international membership. The committee would like to meet with the Director of APA's Office of International Affairs, Ms. Ellen Mercer, at its next meeting to explore increasing the international membership base and related issues.

Membership Termination for Members Eligible for Life Status

The Committee on Membership expressed great concern regarding the termination of membership for nonpayment of local dues of two Southern California Psychiatric Society members who had been members for 33 and 30 years, respectively. Both of these members would have become eligible for Life Member status on Jan. 1, 1992. The chairperson of the committee will write to the president of the district branch to express the sentiments of the committee and to ask the district branch to reconsider these membership actions. The Office of Membership earlier had requested that the district branch reconsider and waive the dues but to no avail.

ACTION ITEMS—GENERAL

Membership Directory

The committee reviewed a proposal from the Council on Research that the production of a membership directory be returned to the Committee on Membership and the Office of Membership. Given the complexities of producing a directory like the previous biographical directories, a number of options were reviewed: publish a smaller directory in-house; continue to use essentially the same approach but publish substantially less information on each member; continue to use the same approach and publish the same amount of information

on each member; collect and correlate a computer-based directory with sale of computer disks or use of a 900 telephone number; contract out the entire data collection, directory publication, and marketing effort.

After considerable discussion, the committee voted to accept the task of holding a feasibility meeting in early 1992 to explore issues surrounding responsibility for publishing a membership directory. The issues involved are many. The task may be complex, and a decision on the direction to be taken should be thoroughly considered in a session with adequate time and with adequate staff resources and background data.

The feasibility study group met in both February and March of 1992 to continue exploration of this question. The group included selected members of the Committee on Membership, the chairperson of the Committee on Biographical Directory and Research on Psychiatric Professional Activities, and selected staff. The group decided that a basic membership directory should be produced in 1994 (possibly to coincide with the Sesquicentennial annual meeting) and that the Committee on Membership and Office of Membership should undertake this project. The study group defined a basic list of items that could be included in such a directory but has not yet determined the final list of what information to collect. Staff is now working to prepare a timetable for this project and several possible budgets.

Military Psychiatrists

The Committee on Membership met with James R. Rundell, M.D., Major, U.S. Air Force, and President of the Society of American Military Psychiatrists. The two membership committees agreed to propose that a worldwide military branch of APA be created. It was noted that military psychiatrists, who number over 450, have already organized themselves into a society functioning in a manner similar to the district branches. The society has about 300 members. APA has approximately 100 military members.

It was felt strongly that military psychiatrists are a unique group because they are subject to frequent and sometimes involuntary relocations, hindering involvement in their geographic communities and hence those district branches. Lack of continued involvement in local district branches disenfranchises this group, makes participation in the governance structure difficult, and inhibits professional contact outside of the military, thereby preventing access to Fellowship. Their day-to-day ties and sense of community are with their military colleagues stationed all over the world and not restricted to the community where they happen to be stationed. The military psychiatrists feel strongly that their "community" consists of their military psychiatric colleagues. Their organization already meets on a regular basis. It maintains a mailing list and produces a periodic newsletter. Military psychiatrists also maintain regular contacts with one another through referrals and WATTS-line communications.

This matter has come before the committee in the past, without closure; however, for the first time the committee is convinced that, because of their establishment of their own organization, military psychiatrists are willing and able to assume responsibilities that are normally associated with the operations of a district branch, including addressing ethical matters, holding regular meetings, and maintaining membership records.

The proposal for a military branch would contain a provision allowing a military psychiatrist the option of belonging to the local district branch in lieu of the military branch. This is akin to a member's being allowed to belong to the district branch where she or he either practices or resides. The Assembly members for this branch would attend meetings of their closest Area councils, as is the case for our minority and Member-in-Training groups. It was the intent of the Committee on Membership that all of the officers of this branch would reside in the United States because of the costs of attending necessary meetings.

In November 1991 the Assembly voted to consider the special membership needs of worldwide active-duty military psychiatrists eligible for APA membership. Among the options to be explored are 1) recruitment for APA membership of the approximately 75% of active-duty military psychiatrists who are not members of APA, 2) facilitating application for advancement to Fellowship and inter-district-branch transfer of existing APA members, 3) enfranchisement in the Assem-

bly, 4) dues issues, and 5) possible creation of a worldwide armed forces district branch. The Assembly further voted to refer this entire matter to the Assembly's Committee on Planning for further evaluation and action recommendations by May 1992. In December the Board of Trustees endorsed the actions taken by the Assembly.

The Assembly's Committee on Planning considered this question when it met in February 1992. That committee plans to invite a member of the Committee on Psychiatric Services in the Military, a representative from the Society of American Military Psychiatrists, and people from the states with large military populations to its 1992 summer meeting.

Work Group on Membership Losses

Dr. Aron Wolf, chairperson of the Ad Hoc Work Group to Advise the Committee on Membership on Membership Losses, reported on the second meeting of the work group, held Nov. 7, 1991. Market research on APA membership and services, suggested by Mr. Rich Feeley (APA consultant), was discussed. The proposal calls for conducting focus groups and a survey as a means of obtaining accurate and meaningful information on member opinions regarding membership benefits (insurance, publications, etc.) and of learning more about factors governing the decision of members to join, or remain in, APA. Focus topics will include fiscal, branch, and publication issues in an attempt to compile comprehensive data in these areas. The estimated cost of such an undertaking is estimated to be around \$100,000; the understanding is that much of this expense would be borne by the APA Insurance Purchasing Group. The balance (estimated to be approximately \$30,000) would be drawn from APA and contributions from other entities (such as the American Psychiatric Press and the Corporation for the Advancement of Psychiatry) in exchange for inclusion of questions that relate to their interests. The data from these marketing studies should become available for possible action in the fall of 1992.

Staff received several proposals from companies experienced in this type of work. One proposal was selected, and the company accepted the contract for the project. Work is now underway on planning a series of focus groups around the country. Information collected from the focus groups will be used to conduct a more extensive survey of the membership on the same subjects. The results of the completed project will be reported to the Assembly and Board of Trustees in the fall of 1992.

Membership Eligibility

The Committee on Membership was asked to review the application for General Membership of a psychiatrist partially trained abroad. This psychiatrist completed residency in the United States and had been accepted for certification examination by the ABPN. The committee would like to recommend to the Board of Trustees that proof of acceptance for examination by the ABPN or the Royal College of Physicians and Surgeons (Canada) be accepted as a method of demonstrating eligibility for APA General Membership for psychiatrists trained outside the United States and Canada. The language to be proposed for inclusion in the "Operations Manual of the Board of Trustees" will be reviewed by the committee at its next meeting.

ACTION ITEMS—MEMBERSHIP PROCESSING

Accreditation by American Osteopathic Association

The Committee on Membership reviewed a request from the Iowa Psychiatric Society regarding eligibility for Member-in-Training (and subsequent General Member) status for an Iowa resident undergoing psychiatric training in a formerly ACGME-approved program now approved only by the American Osteopathic Association. The committee recommended that the resident not be considered eligible for membership unless he enters (and completes) an ACGME-approved training program.

Member-in-Training Advancement in Massachusetts

The committee reviewed requests from the Massachusetts Psychiatric Society regarding the eligibility for membership of two of its

members. The first, a Member-in-Training in an outpatient psychiatry fellowship, trained abroad and did not meet the criteria for advancement to General Membership in the opinion of the Committee on Membership. The second, an applicant for Member-in-Training status, was not deemed eligible for membership by the committee because his training program is not approved by the ACGME. The committee recommended that these membership applications be deferred.

Training Begun Abroad

The New Jersey Psychiatric Association requested that the committee review the application for General Membership of a psychiatrist whose psychiatric training began in Israel and was continued in the United States (the applicant had been accepted for the ABPN certification examination). The committee recommended, on the basis of documentation of U.S. training, that the psychiatrist be accepted for General Membership.

Retroactive Enrollment

A member requested that the Committee on Membership approve a change in his original enrollment date from 1971 to 1970. His application for Member-in-Training was submitted to the Northern California Psychiatric Society on Sept. 20, 1969, and forwarded to APA on March 29, 1971. He was accepted as a Member-in-Training on May 1, 1971. The committee could not find sufficient evidence of any administrative error to justify granting the request and recommended denial.

Fellowship Nominations

The committee reviewed 223 nominations for Fellowship; 182 (81.6%) were recommended for approval by the Board of Trustees (see table 4). The approval rates in 1990 and 1989 were 75.4% and 85.9%, respectively.

Nominations for Honorary Fellowship and Distinguished Fellowship

In accordance with the "Operations Manual of the Board of Trustees," the Committee on Membership acts on nominations by voting members of the Association for Honorary Fellowship and Distinguished Fellowship and forwards its recommendations to the Board of Trustees.

A letter nominating Jean Endicott, Ph.D., for Honorary Fellowship was received from a Fellow of APA. The committee reviewed two additional letters of support and recommended approval of Dr. Endicott for Honorary Fellowship.

A letter nominating Patricia van Ameringen Kind, Ph.D., for Honorary Fellowship was received. The committee reviewed three additional letters of support and recommended approval of Dr. van Ameringen Kind for Honorary Fellowship.

A letter nominating Rachel Gittelman Klein, Ph.D., for Honorary Fellowship was received from a Fellow of APA. The committee reviewed four additional letters of support and recommended approval of Dr. Klein for Honorary Fellowship.

The committee reviewed a request from the Texas Society of Psy-

chiatric Physicians asking for permission to elevate an Associate Member, Leo E. Hollister, M.D., to General Membership even though Dr. Hollister never completed formal psychiatry training and therefore is not eligible for General Member status. The committee concluded, on the basis of Dr. Hollister's very significant and sustained contributions to the field and the strong supporting letters, that Dr. Hollister should be nominated for elevation to Distinguished Fellow. While the committee recognized that the customary procedure for bringing such a nomination to the Board was not followed, it strongly believed that Dr. Hollister met the necessary criteria and recommended approval of Dr. Hollister for Distinguished Fellowship.

Corresponding Members/Fellows

The committee reviewed applications for membership/advancement and recommended that 31 applications for Corresponding Membership and six nominations for new Corresponding Fellows be accepted and that decision on one nomination for advancement from Corresponding Member to Corresponding Fellow be deferred.

Membership Termination for APA Dues Arrears

In compliance with chapter 8, section 7, of the Constitution and Bylaws, the committee recommended that the members whose dues were in arrears for 1990 be dropped from APA membership.

Resignations

Under standing authorization of the Board of Trustees, the Medical Director regretfully accepted the resignations of 370 members during 1991.

Dropping of Members Dropped by District Branches

Chapter 8 of the Bylaws states, "Resignation or loss of membership in the Association or the member's district branch for any reason shall entail loss of membership in both." During 1991, 174 members resigned from or were dropped by their district branches. They were advised that loss of branch membership would involve loss of APA membership. The committee recommended that the Board of Trustees authorize the dropping from APA membership of members who had resigned from or had been dropped by their district branches and, further, that the Board of Trustees authorize administrative reinstatement of those who returned to good standing in their district branches and were also in good standing in APA.

Dues Relief/Inactive Status

The committee reviewed 391 requests for dues relief and/or transfer to Inactive status and recommended approval of 319 and deferral or denial of 72 (see table 4).

Expiration of Medical Student Membership

Numerous Medical Student Members have graduated from medical school, and therefore they have been sent letters notifying them that their Medical Student Membership has expired and, if appropriate, they should advance to Member-in-Training status.

Report of the Committee of Tellers

John Zinner, M.D., Chairperson

The Committee of Tellers met on March 20, 1992, at APA headquarters to certify the results of the 1992 election. Ballots were mailed on Feb. 5, 1992, to 34,715 eligible voting members; from that number 156 undeliverable ballots were deducted. The adjusted number of eligible voting members was 34,559, and 14,260 ballots were returned and included in the final tally (41.3% of the eligible voting members).

The Committee of Tellers acted on uncertain votes that had been held for their decisions. The committee also confirmed that all candidates had verified the accuracy of their biographical statements and had submitted the required statements of compliance with election guidelines.

The Committee of Tellers certified that the following individuals were elected to office and so reported to the Board of Trustees—President-Elect: John S. McIntyre, M.D. (59.6% of the votes cast); Vice-President: Lewis L. Judd, M.D. (57.7%); Treasurer: Mary Jane England, M.D. (69.0%); Trustee-at-Large: Benjamin Liptzin, M.D. (52.0%); Member-in-Training Trustee-Elect: Marian I. Butterfield, M.D. (53.9%); Area III Trustee: Abram M. Hostetter, M.D. (59.7%); Area VI Trustee: Daniel B. Borenstein, M.D. (57.1%).

To have a valid election on changes to the Constitution and Bylaws, 33⅓% of the eligible voting members must cast votes. Abstain and invalid votes are considered to be votes cast and count toward determining whether 33⅓% has been reached. Abstain and invalid votes do not count in determining whether a change passes or fails. Once 33⅓% has been reached, a majority must approve amend-

ments to the Bylaws. The results of the vote on the amendments are as follows.

Amendment 1, chapters 1.13 and 8.6. Votes were cast by 39.3% of the eligible voters. The amendment passed; 66.6% of the votes were in favor. The change removes the dues exemption of members who achieve Life status according to the "rule of 95" in 1993 and thereafter, and it requires them to pay two-thirds dues during the first 5 years after they achieve Life status and one-third dues during the second 5 years. The dues exemption of members who achieved Life status before 1993 continues.

Amendment 2, chapter 6.5. Votes were cast by 39.3% of the eligible voters. The amendment passed; 66.9% of the votes were in favor. The change expands the Nominating Committee to include a representative of a minority/underrepresented group selected in a manner similar to how Area representatives to the Nominating Committee are selected.

Amendment 3, chapter 9.1. Votes were cast by 39.2% of the eligible voters. The amendment passed; 68.3% of the votes were in favor. The change increases the number of signatures required for nomination by petition from 200 to 400 for national office and from 50 to 100 for Area Trustees.

On the recommendation of the Committee of Tellers, the Board of Trustees accepted the results of the 1992 election. The Board also approved a recommendation of the committee to dispose of the ballots from the 1992 election after the 1992 annual meeting.

Psychosocial Rehabilitation and Psychiatry in the Care of Long-Term Patients

Leona L. Bachrach, Ph.D.

The relationship between psychosocial rehabilitation and psychiatry in the care of long-term mental patients is one that may often be characterized, at best, as an uneasy alliance. The author summarizes the basic concepts that define the discipline of psychosocial rehabilitation and discusses how those concepts have at times been distorted in actual practice. The article concludes with an analysis of the two disciplines' common ground in caring for long-term patients and a commentary on the benefits that each may offer the other. Together psychiatry and psychosocial rehabilitation hold the key to improved circumstances for realizing the promise of deinstitutionalization, which seems largely to have eluded us for the past several decades.

(Am J Psychiatry 1992; 149:1455-1463)

During the past several decades psychosocial rehabilitation has achieved prominence as a major service modality in the care of individuals with long-term mental illnesses. Meyerson and Solomon wrote that the field "has received increasing acceptance as a viable treatment approach for those who have severe mental disabilities" (1, p. 1), and Anthony et al. predicted that during the 1990s psychosocial rehabilitation "will assume its rightful place" (2, p. 1).

Yet the relationship between psychosocial rehabilitation and psychiatry in the care of long-term patients is one that may often be characterized, at best, as an uneasy alliance. Although there are certainly service systems and individual agencies in which the two disciplines' offerings are blended to the benefit of the patients whom they serve (3, 4), there are also numerous instances of mutual mistrust. For example, Ryan et al.

wrote that "traditional forms of psychiatric treatment for persons with schizophrenia have led to very poor outcomes" (5, p. 67) and that psychosocial rehabilitation "may well be the preferred way of treating the psychological condition of the person with schizophrenia" (5, p. 83).

To some extent, such statements probably reflect heightened turf concerns (6). An unfortunate result of diminishing resources for the treatment of long-term mental patients may be increased suspicion of the motives of competing disciplines, particularly when interdisciplinary conflict is already entrenched (7, 8). That differences in ideology may be perceived, however inaccurately, as incapable of resolution probably further contributes to the schism. But whatever its source, mistrust between the two disciplines, when it occurs, violates the very basis of multidisciplinary care as envisioned by President John F. Kennedy (9) in the early days of community mental health.

The polarization of psychiatric treatment and psychosocial rehabilitation, in its most extreme form, may be characterized as consisting of two irreconcilable myths. One of these has arisen among certain nonpsychiatric clinicians who hold that rehabilitation is the only kind of modality that persons with long-term men-

Revised version of a paper presented at the Institute on the Role of Community Psychiatry in Psychiatric Rehabilitation, Boston, June 1, 1991. Received Aug. 19, 1991; revision received Nov. 13, 1991; accepted Dec. 5, 1991. From the Maryland Psychiatric Research Center, University of Maryland School of Medicine, Catonsville, Md. Address reprint requests to Dr. Bachrach, 19108 Annapolis Way, Gaithersburg, MD 20879.

Copyright © 1992 American Psychiatric Association.

tal illnesses require and that all other interventions are superfluous, if not harmful. This myth essentially encourages the minimization or even total elimination of psychiatric care for long-term mental patients, and the dangers inherent in it are readily apparent to those familiar with the debilitating effects of severe mental illness. However, a second, equally dangerous myth has arisen within psychiatry, and it holds that rehabilitation philosophy is intrinsically antimedical in its orientation and so must be radically revised, if not eliminated.

In this article I seek to dispel these myths by demonstrating that there is actually a great deal of concordance between the philosophies of psychiatry and psychosocial rehabilitation as they relate to the care of long-term mental patients. I shall argue that the two disciplines need not—in fact, should not—be mutually exclusive. Toward that end, I shall begin with a summary of the basic concepts that define the discipline of psychosocial rehabilitation as it is described in the literature and proceed to a discussion of how those concepts have at times been distorted in actual practice. I shall conclude with an analysis of the two disciplines' common ground in caring for long-term patients and a commentary on the benefits that each may offer the other.

It is probably appropriate for me to state my bias at the outset. I have long been a proponent and student of psychosocial rehabilitation. In fact, my connection with the field of rehabilitation dates back to the time of my first-professional job in the 1950s, when, as a graduate student, I was hired by a facility known today as the Rusk Institute to assist in the piloting of a psychosocial adjustment questionnaire for physically handicapped persons.

Although the terms "psychosocial rehabilitation" and "psychiatric rehabilitation" appear today to be used interchangeably—any distinctions that might once have existed between them have become blurred in the current literature—this article will use the former term and reserve the adjective "psychiatric" to refer more specifically to concepts and interventions that are exclusively associated with the practice of psychiatry.

DEFINING PSYCHOSOCIAL REHABILITATION

The field of psychosocial rehabilitation consists of several different approaches to the care of individuals who suffer from long-term mental illnesses. There are, for example, intradisciplinary differences over what specific training should be required for the credentialing of rehabilitation practitioners, as there are in the degree to which specific modalities, such as behavior modification and psychoeducation, are used.

It is not my intent to comment on the relative merits of these several "models" of psychosocial rehabilitation. Rather, my aim in this article is to focus on their common ground in order to provide readers with a basic, "least common denominator" understanding of the field. This task is, however, complicated by the fact

that, to my knowledge, there is no commonly endorsed definition of psychosocial rehabilitation in the literature (10–12). It is probably not far-fetched to suggest that at least some of the friction which sometimes surfaces between this discipline and psychiatry derives from the fact that, in the absence of a precise definition, psychiatrists' notions about psychosocial rehabilitation are often vague and at times inaccurate.

However, unlike some other occasions in mental health where a single imprecise concept conceals differences that appear to be virtually irreconcilable (13), the several approaches that define themselves as psychosocial rehabilitation appear to share a core of common concepts and values, at least insofar as these are expressed in the literature. This shared philosophy is captured in the writings of Cubelli and Havens (14) and Liberman (15), whose definitions of the field may be paraphrased and summarized as follows: psychosocial rehabilitation is a therapeutic approach to the care of mentally ill individuals that encourages each patient to develop his or her fullest capacities through learning procedures and environmental supports.

ESSENTIALS OF PSYCHOSOCIAL REHABILITATION

As revealed by the field's literature, the philosophy underlying the practice of psychosocial rehabilitation consists of a minimum of eight fundamental and inter-related concepts. Perhaps the most basic of these is the discipline's central goal of enabling an individual who suffers from long-term mental illness to develop to the fullest extent of his or her capacities (6). The word "individual" must be heavily underscored, for psychosocial rehabilitation strongly rejects predetermined, stereotyped, and nonindividual notions of patient care and, first and foremost, emphasizes the need for individually tailored interventions. To express this concept somewhat differently, psychosocial rehabilitation typically rejects questions about what might constitute an appropriate treatment for an entire population of long-term mental patients and focuses instead on what would constitute appropriate care for one specific patient.

Second, in conjunction with individually oriented interventions, psychosocial rehabilitation stresses the importance of environmental factors in the care of people with long-term mental illnesses (16). Because "the essential starting point for a proper understanding of rehabilitation is that it is concerned with the individual person in the context of the environment" (12, p. 3), psychosocial rehabilitation requires either that the patient's capacities be adapted to environmental realities or that the environment be changed to suit the capacities of the patient (17). This focus on environmental concerns also characterizes the practice of clinically oriented case management, which, in addition to providing direct patient care, also encompasses the creation, modification, and adaptation of social and physical environments in order to meet the needs of individuals with long-term mental illnesses (18).

Third, psychosocial rehabilitation is oriented toward the exploitation of patients' strengths (19). Its primary concern, according to Anthony et al., is with "improving the competencies" of people who have long-term mental illnesses (2, p. 64). In fact, this feature of psychosocial rehabilitation is reflected in the position long taken by Lamb, a psychiatrist, who has suggested that clinicians "must work with the well part of the ego" and has contended that "regardless of the extent of psychopathology in evidence, there is always an intact portion of the ego to which treatment and rehabilitation efforts can be directed" (20, p. 7).

Psychosocial rehabilitation is thus eminently positive in its philosophy (12), and this leads directly to a fourth, closely related essential feature of the discipline: the aim of restoring hope to individuals who, because of their psychiatric illnesses, have suffered major setbacks in functional capacity and self-esteem. Anthony et al. have written that "hope is an essential ingredient of psychiatric rehabilitation" (2, p. 67) and have described the focus on hope in terms of the discipline's "future-orientation." This emphasis, as intangible as it is positive, emerges as a distinguishing feature of psychosocial rehabilitation, particularly when it is compared with some of the more traditional psychiatric approaches to the care of patients with long-term mental illnesses (15). Although I know of no formal content analyses to cite in this regard, I would submit that discussions of hope are standard fare in the psychosocial rehabilitation literature but only rarely appear in psychiatric writings on service planning.

The centrality of hope as a concept in psychosocial rehabilitation has been discussed at length by Deegan (21), a clinical psychologist who at one time in her life was hospitalized for schizophrenia: in an address given at a conference in 1988, she said, "For those of us who have been diagnosed with mental illness hope is not just a nice sounding euphemism. It is a matter of life and death." Deegan has revealed that, early in her illness, a loss of hope led her to inactivity and intense depression: "When one lives without hope (when one has given up), the willingness to 'do' is paralyzed as well" (21, p. 13).

A fifth essential concept in psychosocial rehabilitation is its optimism about the vocational potential of mentally ill individuals (2, 22). Van Weeghel and Zeelen (23) in The Netherlands have summarized five advantages of pursuing vocational goals in rehabilitation. First, and most obviously, work provides an income that permits mentally ill people autonomy in gaining goods and services; second, work provides these individuals with the kind of time and space structure that Lamb (20) has described as being critical in the treatment of chronic mental illness; third, work has the potential for broadening the social contacts of mentally ill people; fourth, work provides the person with a readily recognizable societal role; and, fifth, work forces individuals to be active and involved. Similarly, the British rehabilitation psychologist Shepherd has written that work gives the individual patient "a sense of personal achievement and mastery" and that "no other sin-

gle activity is so rich and complex in its psychological, social and material significance" (24, p. 124).

Work is, of course, central to the well-known Fountain House approach to psychosocial rehabilitation, as is demonstrated in the following statement: "Work, especially the opportunity to aspire to and achieve gainful employment, is a deeply generative and reintegrative force in the life of every human being" and, as such, it "must underlie, pervade, and inform" all of the activities surrounding rehabilitation (19, p. 67).

It must be noted, however, that the vocational emphasis in psychosocial rehabilitation is not limited to the pursuit of full-time or competitive employment. For some long-term mentally ill persons the notion of work must be more broadly defined (25-27). Jones, who organized the excellent, but now superseded, Boardwalk program in Denver, has expressed the need for such flexibility in her statement that work opportunities for long-term patients "should address a variety of skills and interests and a variety of physical demands . . . in part because different people have different talents . . . [and in part] because the effects of the illness vary considerably" (28, p. 53). Similarly, van Weeghel and Zeelen have suggested that "vocational rehabilitation does not refer to the regular job market as a single final objective for everybody, but is above all a process with variable elements and differing results" (23, p. 4).

In this connection, supported employment opportunities, which use personal job coaches to provide support to workers and to ensure job backup to employers (29), are important aspects of many psychosocial rehabilitation programs.

Sixth, although psychosocial rehabilitation efforts generally place considerable emphasis on vocational pursuits, this represents only one area of their involvement (30). The field generally views its mission as reaching beyond work activities to encompass a full array of social and recreational life concerns of mentally ill people. Thus, it is not uncommon for psychosocial rehabilitation agencies to sponsor social clubs and to offer resocialization programs and training in social skills. They also frequently provide case management services, as well as various kinds of residential programs, educational activities, community support interventions, consumer-run drop-in centers and businesses, and even family education and support programs (11, 19, 24, 31-35). In short, psychosocial rehabilitation is at heart oriented toward the comprehensive care of individuals with long-term mental illnesses.

Seventh, psychosocial rehabilitation requires that patients be actively involved in their own care and, indeed, in the very design of their own rehabilitation protocols. Thus, in the words of Anthony et al. (10, p. 74), the patient's own "values, experiences, feelings, ideas, and goals" shape the direction of treatment planning during all phases of a rehabilitation intervention. In turn, this requires that the patient be completely informed about the nature of his or her illness, its symptoms, its course, and its possible consequences.

Such an emphasis on patient involvement stands in

direct contrast to interventions and treatments that do "to" or "for" patients, instead of giving them the scope to do "to" or "for" themselves. Peterson, a former patient who has written about his experiences as a member of the renowned Fountain House program in New York City, has expressed this distinction clearly and forcibly in a simple but revealing statement: "For me rehabilitation is not having something done to me" (36, p. 49). Some rehabilitation programs actually go so far with the concept of patient involvement that they are, in effect, consumer-run—and sometimes even consumer-directed—efforts (37).

Eighth, psychosocial rehabilitation is not a one-time-only kind of intervention. It is an ongoing process that must continue over time, and it is conducted in the various settings in which patients find themselves. Hence, rehabilitation programs, although viewed by many persons as having an essential community focus, may also be provided in hospital-based settings; the "where" of a rehabilitation effort is less important than what occurs in a given program and how long that program will be available to the patient (2, 12). Psychosocial rehabilitation is, in short, firmly wedded to the concept of continuity of care (38), a focus that is buttressed by several theoretical underpinnings.

First, there is a strong emphasis on the fact that mentally ill persons exhibit different functional deficits in different social environments. It follows that changes in the external circumstances of these individuals will require ongoing modifications in their basic rehabilitation protocols and that interventions will have to be persistent and flexible (12).

In addition, there is evidence that mentally ill persons generally find it difficult to transfer learned skills and behaviors to new situations (12). Psychosocial rehabilitation must thus "operate on the principle that generalization does not just occur; it must be planned" (10, p. 74).

Moreover, the vulnerabilities of people with long-term mental illnesses are not time limited (unpublished 1990 paper of J.W. Louwrens). To the contrary, they are often lifelong and so require continuing intervention. (The implications of enduring disability for the care of long-term mental patients will be examined more fully in the discussion that follows.)

These eight basic elements of psychosocial rehabilitation, when considered together, suggest that the discipline is, both in theory and practice, prepared to consider and respond to the interaction of a multiplicity of biological, psychological, and sociological factors as they influence the life of a mentally ill individual (31). Thus, psychosocial rehabilitation may be understood to favor a distinctly biopsychosocial approach (39) to the care of people with long-term mental illnesses.

THEORY VERSUS PRACTICE

It is, however, important to note that these theoretical guidelines are not always observed in practice. There is

sometimes a gap between the real and the ideal, just as there may be in the practice of psychiatry with long-term mental patients (40). My own observations during site visits to numerous psychosocial rehabilitation programs throughout the United States have led me to conclude that a few of them are so extremely antimicrobial and antipsychiatric in their outlook that they are, in my judgment, quite dangerous for the patients enrolled in them. These programs strongly resist the use of medications for severely mentally ill individuals and tend to regard the involvement of medically trained personnel as something to be avoided at all costs. In fact, sometimes these efforts are not limited to antimicrobial sentiments; they are also more generally antiprofessional, in that they seem to regard clinical training as something that takes the humanity out of patient care (7).

On a more positive note, it appears to me that such blatantly antiprofessional programs have been decreasing in number. Apparently, an acknowledgment that illness—real illness—underlies psychiatric disability (41) is growing, perhaps in part as the result of the increasing visibility of untreated mentally ill people who now live on the streets. However, some of the biased programs have survived and have unfortunately given psychosocial rehabilitation a bad name. That is why it is extremely important for the field to define precisely what psychosocial rehabilitation is—and also what it is not.

Somewhat less abusive than these blatant denials of illness, but still in my judgment far too antitherapeutic for comfort, is the existence of unrealistic expectations of long-term mental patients in some psychosocial rehabilitation efforts. I have observed a number of instances in which personnel expect mentally ill individuals to accomplish tasks that would be unrealistic for even less disabled persons. I refer specifically to the regimentation that creeps into some programs and virtually forces mentally ill people always to do something, to complete something, to go somewhere, or to be somewhere. Of course, rehabilitation is by its very nature task oriented; that is a given. But it seems obvious that there must be a limit to the pressure that is placed on patients to perform.

Another antitherapeutic practice exists in the tendency of some psychosocial rehabilitation efforts to close their gates—and, more importantly, to close their consciousness—to the most severely disabled mentally ill individuals. As a matter of fact, it is not the gatekeeping *per se* that is troublesome; few if any programs fail to exercise some control, however minimal, over admissions. What is of concern, however, is the existence of programs that purport to keep no gates but then proceed to admit only individuals who appear to fit in with their special offerings—a practice that sometimes leaves patients who do not fit with no alternatives for treatment.

Such gatekeeping practices are closely related to still another difficulty: the tendency of some psychosocial rehabilitation programs, despite lip service to flexibility, to place such heavy emphasis on the vocational aspects of rehabilitation that other important concerns

become minimized. Speaking of rehabilitation for physically disabled persons, Litman (42) cautioned that, when programs are too focused on vocational objectives, they may become "dominated by a utilitarian goal of employability." This systematically discriminates against persons who are unemployable.

Litman's concern is as valid for psychiatric patients as it is for physical medicine patients. For one thing, external economic circumstances, as well as the degree of competition within the labor force, may severely curtail employment opportunities for mentally ill people (30; unpublished 1990 paper of J. van Weeghel). Additionally, the stresses that these individuals sometimes suffer when their efforts to find work are unsuccessful may be quite harmful, particularly when competitive employment is held up as the ultimate goal for every person.

I mention these issues not because they are intrinsic to the practice of psychosocial rehabilitation or even necessarily illustrative of mainstream thought in the field but, rather, because, when such negative practices occur, they serve mentally ill individuals poorly. Moreover, these negative practices—these departures from the ideal—are completely antithetical to the fundamental philosophy of psychosocial rehabilitation as it is portrayed in the extensive literature of that field. In fact, from the point of view of that literature, it may well be an error to define the efforts that foster such practices as rehabilitation programs. Yet, in the absence of a standardized definition of what the field encompasses, there is nothing to stop them from identifying themselves in this way.

On a more positive note, even a cursory review of the literature suggests that these problems are increasingly being acknowledged within the field of psychosocial rehabilitation. This gives us hope for their amelioration. Lamb (20) has been particularly forthright in identifying these kinds of issues and in cautioning against what he has termed the "overselling" of rehabilitation. Fortunately for all concerned, Lamb's writings continue to have considerable impact on service planning for long-term patients.

CONCEPTS IN PSYCHIATRIC CARE

One of the most harmful effects of the negative practices I have described is that they reinforce an impression that the disciplines of psychosocial rehabilitation and psychiatry lack a common meeting ground. Is such a conclusion valid? To answer this question I have selected two major conceptual developments that influence the psychiatric treatment of long-term mental patients today (43), and I shall use these as yardsticks for establishing the degree of fit between the two disciplines. I shall first comment on the psychiatric concept of individualized treatment planning for long-term mental patients and then examine a psychiatric approach to the understanding of disability among the members of this patient population.

My choice of the psychiatric concept of individualized treatment planning may perhaps appear gratuitous. Does it not go without saying that psychiatric care will be administered with a focus on the individual patient? Unfortunately, this has not always been the case, as is apparent from the frequency with which "dumping" of long-term mental patients has occurred. These patients have frequently been placed in institutions and provided, at best, with only stereotyped programming. What is more, they have often fared no better in their community placements (44). Indeed, the fact that the mental patients who need the most comprehensive and sophisticated care have historically been given the least individualized treatments has become a source of great concern to many psychiatrists (40). (I might add that, as an involved nonpsychiatrist, I believe the future credibility of psychiatry will rest largely on its ability to organize individually tailored treatments for long-term patients as effectively as it has in the past for patients who are less severely disabled.)

It is encouraging to note, however, that in recent years the psychiatric literature has shown increasing concern with the need to accord individualized attention to long-term mental patients (38, 45). The concept of individualized treatment planning is now widely endorsed and forms a potential bridge between the practice of psychiatry and that of psychosocial rehabilitation. As noted earlier, the basic orientation of rehabilitation is toward the individual patient—toward realistically assessing that person's strengths and disabilities and working from there to maximize his or her potential. Thus, it seems unnecessary to belabor the point: the fit between psychiatry and psychosocial rehabilitation respecting this particular concept leaves little if any room for theoretical dissonance.

Indeed, the fact that both disciplines speak with a single voice on this issue is most encouraging. Whether it gets its impetus from psychiatry or psychosocial rehabilitation, the acknowledgment that programmatic interventions must stress the needs of a mentally ill *person*, and not the needs of a mentally ill *population*, is a major step forward in service planning. It is even possible that this is the most important advance in service planning for long-term patients over the past several decades (45), and the concordance between the two disciplines in this regard is readily apparent.

The relationship between the psychiatric concept of disability and the practice of psychosocial rehabilitation is somewhat more complex, although it too suggests considerable congruence between the two disciplines. Increasingly today, disability is viewed as having multiple sources that subsume, but extend beyond, the direct effects of psychopathology. There have been several formulations of this position in the psychiatric literature, including the focus on impairment, disability, and handicap that is largely associated with the rehabilitation approach of Liberman et al. (15, 16). As a sociologist, however, I am drawn to the particular constructs and terminology used by two British authorities; Wing and Morris (46).

Wing and Morris have described three essential varieties of disability that typically affect severely ill long-term mental patients. The primary disabilities are those associated with the illness per se; they consist of dysfunctional behaviors or characteristics that may otherwise be described as symptoms of illness. For example, people diagnosed with chronic schizophrenia might exhibit such primary disabilities as lethargy, odd and unacceptable behavior, a lack of awareness of their handicaps, and disturbances in their social relationships. It is typically the appearance of these symptoms of illness that leads to diagnosis and, for many individuals although not all, to treatment in the system of care.

Building on the primary disabilities are secondary disabilities that come not from the illness per se but from the *experience* of illness. Wing and Morris have referred to these as "adverse personal reactions," and their essence was eloquently captured in an anonymous patient-authored article that appeared in the *American Journal of Psychiatry* several years ago: "Even if medication can free the schizophrenic patient from some of his torment, the scars of emotional confusion remain, felt perhaps more deeply by a greater sensitivity and vulnerability" (47).

Wing and Morris (46) have suggested that secondary disabilities may present as much of a problem for successful engagement and treatment of the long-term patient as do the primary symptoms of the illness itself. In fact, a critical point to keep in mind regarding secondary disabilities is that they are often difficult to overcome. In Shepherd's words, "a major psychiatric episode is a frightening and disturbing experience and its effects may persist long after the primary symptoms have disappeared" (24, p. 5).

Finally, there is a class of tertiary disabilities that Wing and Morris (46) call "social disablements." These come not from the illness per se, nor are they personal responses to illness. Rather, they are external to the patient and come from societal reactions to mental illness. Accordingly, the tertiary disabilities include such circumstances as diminished social networks, stigma, poverty, unemployment, and the general absence of a place in society.

A most succinct and moving description of tertiary disabilities was provided at a meeting in 1987 by a former mental patient, Esso Leete:

Sadly, in addition to handicaps imposed by our illnesses, the mentally disabled must constantly deal with barriers erected by society as well. Of these, there is none more devastating, discrediting and disabling to an individual recovering from mental illness than stigma. We are denied jobs, unwanted in our communities. We are seen as unattractive, lazy, stupid, unpredictable, and dangerous.

Inevitably, these societal responses spill over into the mental health service system and are manifested in program offerings for long-term patients that are frequently irrelevant and sometimes downright discriminatory and preclusive.

Lewis, an internist, described the biopsychosocial perspective as one that "frees us from biologically overdetermined and restrictive criteria and from vague definitions of disease" (48, p. 262). It is clear that such a concept is entirely consistent with the psychiatric formulation of disability described here—an approach in which biological, psychological, and sociological elements in interaction are understood to give rise to the problems experienced by long-term mental patients. Moreover, it seems obvious that such a concept of disability must also be entirely compatible with the philosophy of psychosocial rehabilitation, which is equally biopsychosocial. Both suggest that clinical interventions which can affect the lives of long-term mentally ill people in a positive and lasting way depend on the clinician's ability to respond simultaneously to all their sources of disability, not just their illnesses (16, 49).

TOWARD A COMMON FOCUS

Given this commonality in outlook, how may the two disciplines actually share in the clinical care of long-term mental patients? At the first level of disability—the level of the primary symptoms—programs that make the most effective use of pharmacotherapies are needed, for it is the competent and judicious prescription and monitoring of drugs that may start the reversal of primary symptoms and thus allow intervention at the other levels. Obviously, the medically trained psychiatrist has a basic role to play with respect to primary disabilities.

The psychiatrist also has an obvious and essential role with reference to the secondary disabilities by helping patients to understand, accept, and come to terms with their illnesses. In fact, psychiatry and rehabilitation can, and should, work together in this regard. They must make available to each patient a variety of interventions that will help him or her to respond more realistically to the fact of illness. This includes providing individual and group psychotherapy, counseling, psychoeducation, and, in the most basic way, a full array of rehabilitative interventions that relate to skills training, behavioral change, and environmental adaptation.

Areas of overlap between the two disciplines are also evident with respect to the tertiary disabilities. It is essential that agencies providing services to long-term mental patients seek to improve overall quality of care, enhance patients' social networks, minimize the negative effects of gatekeeping, and attempt to reduce stigma within the mental health professions and society at large. Rehabilitation, with its concept of engineering environmental change, effectively legitimizes the professional person's role in these kinds of efforts. Rehabilitators, psychiatrists, and everyone else involved in the care of long-term mentally ill individuals must be prepared to pressure the service system, from within and without, to alter its practices and become responsive to the social disablements of these individuals.

The Dutch psychiatrist F.M.J. Woonings, in an un-

published 1990 paper, defined psychosocial rehabilitation as "a process in which skills are being learned to cope with permanent disability." At first glance, non-psychiatrists might regard such a definition—one that is proffered by a psychiatrist and stresses the permanence of psychiatric disability—as unduly pessimistic. However, if considered in the context of Wing and Morris's concept of disability, this definition is entirely realistic. Since disability is not limited to circumstances that arise directly from the illness but also includes psychological and sociological elements, and since the latter may persist independently over time, the notion of permanent disability is entirely credible. What is more, it is absolutely consistent with rehabilitation's emphasis on continuity of care.

UNDERSTANDING THE CONFLICT

The foregoing discussion suggests substantial areas of compatibility between psychiatric and psychosocial approaches to the care of long-term mental patients. It is important to note that there exist a number of clinical settings in which that compatibility is put into practice and the two disciplines work together cooperatively and successfully. Some, like Liberman's programs (15), actually foster a blurring of the boundaries between the disciplines. The fact that instances of dissonance are often sounded loudly does not mean that they necessarily dominate in the relationship between the two fields.

But some dissonance does exist, and as noted previously, a portion is probably attributable to turf concerns that have become exacerbated by diminishing resources. The fact that it is difficult to know precisely what a psychosocial rehabilitation program is probably contributes to the dissonance as well: as we have seen, some programs that do not honor the philosophy of the discipline bear that name.

However, there is still another factor that may explain some of the interdisciplinary conflict. This is the fact that the comprehensive role of each discipline is inadequately understood, or perhaps not accepted, by the other. For example, proponents of psychiatric rehabilitation sometimes, and inaccurately, see psychiatry as following rigid "medical model" practices in the care of long-term mental patients; they overlook the fact that the biopsychosocial approach is but one of several medical models and is particularly supported by psychiatrists who work with this patient population.

Additionally, it is likely that a certain amount of conflict is related to the fact that psychosocial rehabilitation has been viewed primarily as tertiary prevention (16, 50, 51)—as part of a class of interventions that follow active treatment. It is not surprising that rehabilitation practitioners have become somewhat sensitive to this characterization of their work, a view that they feel, perhaps accurately, has been fostered by psychiatric clinicians and that minimizes their contribution during the active phases of a patient's illness.

Gittelman (52) has, however, proposed an alternative

view, one that establishes psychosocial rehabilitation as part of secondary prevention—as part of treatment instead of something that follows treatment. This notion, which is also reflected in the writings of Fine (6), a prominent occupational therapist, is almost certainly more in line with psychosocial rehabilitation's existential view of its mission and is worthy of serious consideration by psychiatrists.

In many ways, however, the controversy over boundaries is basically a meaningless one, a fact that Black recognized and cautioned against in 1978: "It matters little whether one considers rehabilitation as part of a total treatment or mental health approach . . . or whether one thinks of rehabilitation as the totality of the endeavor of which the medical and psychiatric treatment is a part. The fact is that there must be a joining of resources" (32, pp. 308–309).

REHABILITATION'S INTEGRATIVE FUNCTION

Many rehabilitation practitioners will readily acknowledge that the field of psychosocial rehabilitation depends on psychiatry in a number of ways. They understand, for example, that unless the primary symptoms described by Wing and Morris are under control, rehabilitative interventions are likely to have little success. They also acknowledge that in the case of illnesses with episodic exacerbations, it is essential to have medically trained personnel who are able to sort out the sources of patient dysfunction. Many also accept the critical importance of providing psychiatric therapy, individual and group, to long-term mental patients even as they are enrolled in psychosocial rehabilitation programs.

But what is the trade-off for psychiatry in allying itself with psychosocial rehabilitation? I would submit that, for psychiatry, there is valuable support to be found in the philosophy, goals, and practice of psychosocial rehabilitation. Psychosocial rehabilitation is, in essence, an integrative discipline in several different senses, all of them important for the practice of psychiatry.

First, psychosocial rehabilitation is integrative for patients in a psychological sense, in that it fosters wholeness in the individual. When it is pursued realistically and in a manner consistent with its philosophical foundation, psychosocial rehabilitation enables patients to develop a sense of hope and purpose that supplements—and may even enhance—more traditional treatment approaches. In this sense, psychosocial rehabilitation supports the goals that psychiatry holds for patients: to "live, love, and work meaningfully and productively in the world" (3). What is more, in the words of Gittelman and Freedman (53), if psychiatrists fail to support rehabilitative interventions, they will find themselves "treating only half the illness."

Second, psychosocial rehabilitation is also integrative for patients in the sense that it assists them in finding their place in the community. With its environ-

mental focus, psychosocial rehabilitation provides these individuals with the learning and skills that are necessary for societal integration. And with its emphasis on continuity of care, it helps ensure that those skills are constantly updated. This is entirely consistent with psychiatry's aim of enabling mentally ill individuals to function optimally in community-based settings. Needless to say, such societal integration cannot be complete for all patients, for we are not at present able to restore all mentally ill persons to full societal functioning. But even for patients whose integration will be marginal, rehabilitation represents a starting point. At the very least, it can provide positive experiences and hope for many people who suffer from long-term mental illnesses.

Third, from the point of view of the psychiatrist who seeks to reinforce his or her connection with other medical specialties, having a rehabilitative focus may serve still another integrative function. Anthony et al. (2) have shown that there is a close connection between the essentials of psychosocial rehabilitation and those of rehabilitation for physically disabled individuals, and Deegan wrote, "From the perspective of the rehabilitation approach, it is no longer necessary to isolate the psychiatrically disabled as totally different from other groups of persons with disabilities" (21, p. 11). Thus, psychosocial rehabilitation offers a tangible point for consensus and cooperation among medical specialty groups.

Finally, psychosocial rehabilitation provides an integrative focus for the interdisciplinary care of people with long-term mental illnesses (2, 17). It is what Grob described as "a many-sided and multidisciplinary process" (51, p. 271), and, as such, it is entirely in keeping with the goals set forth for community health as they were expressed in President John F. Kennedy's 1963 statement (9) on a "bold new approach" in mental health service delivery.

These are too many "integrations" to ignore. The field of psychosocial rehabilitation is important to psychiatry—and vice versa—for so many different reasons that it is foolhardy to focus more on differences than on areas of concordance (54). Whether one considers psychiatric treatment and rehabilitation as two separate approaches or as two parts of a single approach in patient care, they need not be viewed as mutually exclusive. To the contrary, psychosocial rehabilitation and psychiatry can be, and must be, blended, a position that is underscored by the fact that a number of conscientious and respected psychiatrists—among them, Douglas Bennett, H. Richard Lamb, Robert Liberman, Dennis McCrory, Arthur Meyerson, John Talbott, and John Wing—are themselves deeply involved in the theory and practice of psychosocial rehabilitation.

A recent review of the literature on rehabilitation outcome supports the notion that psychiatry and psychosocial rehabilitation complement each other's contributions to the improvement of long-term patients' life circumstances. Although this body of research is limited by the absence of common definitions and out-

come measures and although its validity is generally confounded by the interactive effects of psychiatric and rehabilitative interventions, the existing evidence nonetheless points strongly to the conclusion that both disciplines must be integrated "to help patients achieve maximum feasible adaptation" (15, p. 23). I would submit that, together, these disciplines hold the key to realizing the promise of deinstitutionalization, which seems largely to have eluded us for the past several decades.

The Psychoanalytic Conceptualization of Perinatal Loss: A Multidimensional Model

Irving G. Leon, Ph.D.

Much has been learned about perinatal loss over the past 20 years through clinical investigations and quantitative research. However, a review of studies over the past decade reveals that perinatal loss is increasingly being seen in the same way as a death of any other member of the family, rather than as a unique bereavement. A comprehensive understanding of perinatal loss anchored in a theoretical framework of pregnancy is lacking. This article offers a multidimensional model for examining this loss by applying four psychoanalytic interpretations of pregnancy. 1) From the perspective of pregnancy ushering in the new developmental phase of parenthood, perinatal loss becomes a developmental interference, disrupting a significant milestone as well as causing isolation from peers. 2) In light of the usual recapitulation of earlier conflicts during pregnancy as noted by drive theory, perinatal loss may lead to an intensification of intrapsychic conflicts. 3) Understanding pregnancy as the creation of a specific person in an object relations model highlights the importance of mourning after perinatal death, as well as the need to tend to associated unresolved grief from earlier losses. 4) Finally, a model of narcissism describes how pregnancy reorganizes self-esteem, thereby delineating the intense narcissistic injury and rage that often follow perinatal loss. These multiple frameworks help to explain the many repercussions of this loss as well as to account for individual differences. Research findings are selectively reviewed to support the validity of this model. Conversely, this model may productively guide future avenues for research.

(Am J Psychiatry 1992; 149:1464-1472)

Over the past 20 years there has been a dramatically increased awareness of the grief that usually follows perinatal loss. However, our understanding of the unique dimensions of perinatal loss and exactly what it means to the bereaved family is often sketchy and incomplete. Many anecdotal reports based on interviews with bereaved parents (usually mothers) richly illustrate the affective nature of this grief—the initial shock followed by hurt, rage, yearning, disappointment, and pervasive guilt—as well as common behavioral manifestations in psychosomatic symptoms of depression (1–6). A growing body of quantitative studies is attempting to determine the variables that predict adaptive versus more pathogenic forms of grieving (7–17). Few studies, however, anecdotal or quantitative, offer a comprehensive theoretical framework in which to anchor clinical observations of affective, cognitive,

and behavioral functioning as well as to direct meaningful research questions suitable for quantitative evaluation. We may know a lot about perinatal loss while understanding very little about what this death means to the bereaved. This article attempts to provide a multidimensional psychoanalytic framework in which to integrate clinical and research findings on perinatal loss. It builds on previous works in this area (18–21) by describing how contemporary psychoanalytic perspectives of developmental stages, drives, object relations, and narcissism may deepen our understanding of perinatal loss and guide research. The article does not offer a systematic review of the empirical literature, which is available elsewhere (18, 22, 23).

In the United States, perinatal loss is generally defined as all reproductive losses occurring between the twentieth week of pregnancy and the first month of life (24), including late-term intrauterine fetal death, stillbirth, and neonatal death. In this article I also view earlier pregnancy losses (i.e., miscarriage, ectopic pregnancy, and termination of pregnancy after learning of severe fetal abnormality) as perinatal losses but do not consider elective abortion, which is distinguished by very different reactions (18).

Received July 26, 1991; revision received Dec. 18, 1991; accepted Jan. 17, 1992. RECENT CONCEPTIONS OF PERINATAL LOSS

Early studies of perinatal loss highlighted the failure of physicians and nurses to recognize the usual grief and need to mourn following perinatal death. In his now-classic study, Bourne (25) described how stillbirth was typically regarded as a "non-event" by medical caregivers, who were significantly less able to recall such deliveries than the healthy births they had attended. Throughout the 1970s, investigators decried the failure of medical caregivers, families, and friends to recognize and appropriately respond to perinatal loss (26–30), while they noted how such professional and societal indifference could both intensify parental distress and interfere with the resolution of grief (31–33). Many of these studies considered how being oblivious to parental grief could serve the medical caregiver's defensive needs to deny his or her own grief, disappointment, and/or guilt.

More phenomenologically oriented case reports highlighted how perinatal loss is a unique bereavement, stemming from the incomplete separation of mother and baby and leading to a sense of the loss of a part of oneself (34–36) and an intense investment in fantasy in relating to the unborn child (37, 38). However, perinatal loss was increasingly considered much like the death of any other member of the family (23) in terms of mourning the baby as a distinct other (i.e., object loss) rather than a part of oneself. This became evident in a number of ways in the mounting number of studies in the 1980s. Many quantitative studies began to rely on grief measures developed for other bereavements, such as death of a spouse or child, implicitly not regarding perinatal death as a significantly different phenomenon (8–10, 13). While the earlier descriptive studies of the 1970s highlighted the importance of pregnancy in understanding the meanings of perinatal loss, most studies in the 1980s made scant reference to this particular physical and emotional context. Perinatal loss became subsumed within the grief literature as a specific, though not particularly distinct, death.

An understanding of this kind of death needs to include a greater appreciation of its occurrence at the inception of life. Most researchers recognize, of course, that this death is significantly different from other losses in that the bereaved parents have had no opportunity to identify and get to know their baby, through interactions, as a specific, real person who can be mourned. This fact explains the often crucial value placed on viewing and holding the child for providing memories to facilitate grieving. Zeanah's very thorough literature review (22) noted the failure to distinguish adequately the nature of perinatal loss from other family deaths but provided no discussion of how pregnancy may importantly influence the experience of this loss. This is all the more striking in light of the significant work of Zeanah and associates on the development of parental attachment in the last trimester of pregnancy (39, 40). There is a notable discrepancy between researchers' implicit recognition of how peri-

natal loss is unique and their overt failure to translate that understanding methodologically into appropriate measures and interpretively into the theoretical context of pregnancy.

By 1992 the omission of pregnancy from the meaningful investigation of perinatal loss appeared as striking as the repression of memory (and grief) that Bourne (25) had noted about these deaths more than 20 years earlier. While researchers are now able to regard these losses as being as important as other family deaths, they still tend to overlook the ways in which they are different.

A MULTIDIMENSIONAL APPLICATION OF PSYCHOANALYTIC THEORY

I now offer a broad psychoanalytic orientation to highlight the value of an intrapsychic perspective in appreciating the multiple aspects of perinatal loss and in guiding research. Four distinct psychoanalytic frameworks can be used in understanding the meanings of pregnancy and the impact of perinatal loss. Pregnancy may be interpreted alternatively as a developmental milestone, a revival of earlier instinctually charged conflicts, the creation of a new object relationship, and an enhancement of the self. Similarly, perinatal loss can be understood by each of these frameworks as, respectively, a developmental interference, intensification of earlier conflicts, object loss with particular obstacles to mourning, and multiple narcissistic injuries. By orienting to models of adult development, drives, object relations, and self, different aspects of experience (e.g., self versus other) and levels of conceptualization (e.g., biological versus psychological versus cultural) can be considered.

This dissection of psychoanalysis is similar to Pine's depiction (41) of the four psychologies of psychoanalysis—drive, ego, object, and self. While my dimension of drives combines drive and ego into the generally accepted integration of ego psychology, the additional application of developmental stage highlights the centrality of pregnancy and parenthood as a new opportunity for reorganization and revision (rather than only the repetition of issues and identifications in the earlier developmental stages embedded in the other models). Pine (41) has argued that these dimensions can be viewed alternatively as separate psychologies, with an individual developing a unique life history of each, or as different perspectives on the same phenomena, with an increasingly complex web of interacting links. Similarly, I believe that it is useful to preserve the individual integrity of these dimensions in order to highlight how these diverse aspects of pregnancy and perinatal loss may assume a different hierarchical salience among different people; for some, the developmental interference in one's wish to be a parent may be paramount, while for others the loss of the particular child (or the blow to one's self-esteem) may be central. It is especially important to challenge the common implicit assumption that

object loss is the sole or primary dynamic after all perinatal losses. The unique mosaic of developmental wishes, internalized conflicts, complexion of object representations, and narcissistic needs involved in each pregnancy and its loss makes each an individual experience. The different languages and points of reference each model uses also encourage this differentiation. At the same time, these perspectives can be integrated on a higher conceptual level, demonstrating their mutual reinforcement of broader themes as well as their complementarity (18).

Developmental Model

As a new developmental stage, pregnancy typically precipitates a psychosocial crisis in one's internal constellation of representations, conflicts, and fantasies, which interact with the cultural (and subcultural) changes in identity that are induced by becoming a parent. Both intrapsychic and societal dimensions need to be considered. Psychoanalytic theorists such as Deutsch (42) and Benedek (43) have described the maturational importance of pregnancy as a preparation for parenthood that can help establish a more secure and independent sense of adult identity, rooted, paradoxically enough, in a revived reconciliation with one's early childhood experiences. Bibring and her colleagues (44, 45), more than any other theorists, delineated pregnancy as a crisis, with regression providing the essential opportunity for consolidating earlier conflicts, identifications, and issues in a new organization of the personality. As in adolescence (46), the presence of psychological upheaval and distress typically indicates a regression that may not be an indicator of pathology but a prelude to constructive resolution. Some of Bibring and Valenstein's (45) and Ballou's (47) case illustrations offer good examples of how seemingly disturbed and symptomatic reactions during pregnancy presaged more successful adaptation than had been achieved before. Family theorists (48-50), on the other hand, apply a transactional model in which pregnancy, as a transition to parenthood, alters the balance of marital and gender roles that had been established, leading to new interactional patterns and conflicts. The focus here is not on intrapsychic adjustment but on the accommodation of new role demands with previously set modes of satisfaction, communication, and intimacy.

In his classic study delineating the eight stages of human development, Erikson (51) highlighted the crucial role of generativity, typically—although not exclusively nor even necessarily—realized through parenthood:

In this book the emphasis is on the childhood stages, otherwise the section on generativity would of necessity be the central one, for this term encompasses the evolutionary development which has made man the teaching and instituting as well as the learning animal. The fashionable insistence on dramatizing the dependence of children on adults often blinds us to the dependence of the older generation on the

younger one. Mature man needs to be needed, and maturity needs guidance as well as encouragement from what has been produced and must be taken care of. (pp. 266-267)

This quotation underscores the importance of this particular developmental stage as a distinctly influential period that is not reducible to simply another step in the sequence of drive, object, or self development. Furthermore, it beautifully describes the reciprocal influences between parent and child in parental intrapsychic development, as illuminated by Benedek (52), and foreshadows later studies of infant behavior demonstrating how much infants influence (as opposed to being only affected by) their parents (53). Finally, Erikson (51) clearly indicated how this developmental stage emerges at the crossroads of intrapsychic and social maturation: "Generativity thus is an essential stage on the psychosexual as well as on the psychosocial schedule" (p. 267). Appropriately, *Childhood and Society* is dedicated "to our children's children."

Occurring during pregnancy, perinatal loss is a crisis within a crisis. The heightened vulnerability during such an intensified crisis may tax the woman's coping capacities (i.e., ego resources), thereby increasing the importance of "social support" (a too-often undefined concept). The commonly reported significance of available, empathic, and concretely helpful figures—especially husbands (7, 9, 10, 14) but also professional caregivers (7, 12, 29, 33, 54, 55)—in facilitating a more adaptive recovery from perinatal loss may be based on the increased maternal disorganization during this developmental crisis. Many usual responses to perinatal loss, such as visualizing or hearing a baby, the intense wish to have another baby as soon as possible, and the intolerable pain on being exposed to any and all reminders of babies (1, 23, 56), may be due less to the loss of a particular person than to the major disruption in developmental progress caused by this loss—especially if it is a first pregnancy. Perinatal loss is often a developmental interference that intensifies the desire to get back on track developmentally by having a baby to secure one's parenthood.

In addition to the intrapsychic repercussions of failing to achieve the developmental goals of this stage (i.e., "a pervading sense of stagnation and personal impoverishment" [51, p. 267]), perinatal loss often fosters profound interpersonal exclusion from the activities of childbearing friends and siblings. Deprived of this usual support network, the childless couple must now cope with an increased isolation due not only to the loneliness of grief but also to the additional sense of there being no place for them in a community of families. (While some of this discussion applies to perinatal loss after healthy births, since parenthood is a developmental process not achieved all at once, the developmental implications and interference are likely to be more profound when the loss is the first wanted pregnancy.) The value of a support group in easing the pain and promoting understanding of perinatal loss may not be restricted to the usual goal of facilitating

grief (1, 5, 56–58) but, just as importantly, it may provide a reference group that bereaved parents can join and belong to.

Drive Model

Pregnancy can be considered an instinctual process in both the correspondence of hormonal (i.e., progesterone) production with an introverted oral mode of functioning (59) and the recapitulation of infantile sexuality (i.e., oral, anal, and phallic expression) coinciding with each trimester of pregnancy (42, 44, 60, 61). While the first perspective approaches a purely physiological, biological interpretation linking psychosexual orientation to hormonal production, the second view seems traditionally psychoanalytic in basing psychosexual expression on the interface of biology and psychology through the concept of drive (i.e., libido). The two understandings, however, are united by the centrality of sexuality; the first biological version may be associated with Freud's earlier ambition (and heritage as a neurologist) to create a completely physicalistic paradigm of psychic functioning before he developed the psychological machinery embodied in the libido theory, the structural model, and ego psychology (62, 63).

Many researchers have poignantly captured the intense, quite visceral yearning of the bereaved mother for physical contact with her dead child (23, 37, 38). Peppers and Knapp (1) observed that "mothers say they yearn to embrace their baby; their arms ache to hold the baby; their breasts ache to nurse the baby" (p. 42). The profound and quite literal hunger of the mother to nurture her baby is rooted in the normal oral mode during pregnancy, which has been frustrated and denied by perinatal loss. Intensified deprivation can lead to severe depression, which may be based less on a specific object loss (as most researchers suggest) than on the orally regressed state of pregnancy in which this loss occurs. The mother's powerful need to hold, feed, and care for her child cannot be based on prior memories of those actual interactions (the usual content of grief after object loss) but draws on cherished maternal and infantile wishes fueled by both the regression to the oral subphase within pregnancy and the deprivation caused by the child's death.

The revival of "unfinished business" in pregnancy may invite the bereaved mother to construct distorted, maladaptive understandings of her perinatal loss based on earlier conflicts. There are many psychotherapeutic case examples of maternal perinatal loss becoming linked with earlier, unresolved oedipal conflicts, the bereaved mother's ambivalence toward her own mother, and unresolved separation-individuation issues (18). Although other clinicians have described the benefits of some form of counseling or psychotherapy after perinatal loss (64–68), virtually all of them have focused on the circumstances and importance of mourning this often inaccessible object loss, neglecting much consideration of the internalized conflicts revived by the loss.

Object Relations Model

This perspective highlights the primacy of human relationships with an internal world of object representations guiding motives, epitomized, for our purposes, by Bowlby's model of attachment (69). By the last trimester of pregnancy, an intense attachment to the unborn child as a separate, distinct person usually develops (39, 40, 70–73). This perspective involves, moreover, not only seeking a new object (one's child) but reviving, reclaiming, and reorganizing early object ties, as a baby, to one's mother and, as a mother, identifying with maternal figures both past and present. The handiwork of earlier psychoanalytic theorists such as Deutsch (42), Benedek (74), and Bibring (44) displayed threads of drive and object relations inextricably woven together. More recent investigators have tended to emphasize the centrality, if not primacy, of the earliest relationship with one's mother over the drives in determining the course of pregnancy (47, 75). Sometimes the differences between these two perspectives are highlighted, leading to their definition as divergent orientations, depending on whether controlling the drives or resonating with the other is ascendant (76).

Most theorists focus on how perinatal death is the loss of a cherished, distinct other and recognize how mourning is complicated by the lack of memories and interactions with the dead baby, the lack of professional and familial support for grieving over this loss, and the unexpected suddenness of the death, which often leaves parents feeling confused and disoriented, sometimes doubting the reality of both the pregnancy and the death (31, 32). It logically follows that naming, seeing, holding, and burying one's dead child can significantly facilitate mourning by promoting the creation of a distinct identity for this child as well as by making both the pregnancy and the death more real. Not surprisingly, virtually every researcher who has studied perinatal loss and every clinician who has worked with these parents strongly endorses providing opportunities for parents to make the reality of the dead child be recognized and encourages bonding to the newborn so that it can be more completely mourned (1, 5, 18, 23, 31, 32, 35, 37, 38, 55, 56, 77). However, in focusing exclusively on the loss of this specific child, additional object ties—such as an unresolved parental death in childhood—associated with the pregnancy and now the death of this child are overlooked. There are numerous cases in which depression associated with earlier unresolved grief, especially for a mother or maternal figure who died in childhood, was precipitated by perinatal loss (18). Because pregnancy involves not only seeking a new child but also resurrecting important parental relationships, mourning perinatal loss requires resolving the grief for the child who has died *and* the legacy of past object images conferred upon that child.

Narcissism Model

Just as the fetus is physically a part of the mother, the unborn child initially is experienced much more as

a part of the mother's self than as a separate person. While over the course of pregnancy (and especially at birth) the balance shifts as the child is viewed as an increasingly distinct individual, the mother's narcissistic experience of her child remains throughout that child's life as a vital and unique ingredient of parental attachment. Mothers invest a considerable portion of their self-esteem in the child-to-be. Deutsch (42) observed, "Pregnancy is a welcome opportunity to enhance their own importance" (p. 156). "Often it [the fetus] appears as an ideal child, usually representing the dreamer herself endowed with her own best qualities and all those she would like to have" (p. 162). I have discussed at length (18) how pregnancy fulfills crucial narcissistic ambitions by 1) fostering the achievement of omnipotence, both in the act of creation and in becoming a mother, who is imbued with such power in the mind of a young child, 2) affirming one's femininity through reproduction, and 3) serving as a vital narcissistic defense against death anxiety through a sense of immortality because of one's biological continuity in the next generation. Kohut's concepts (78) may help explain how an expectant mother's self-esteem can be regulated by the experience of her unborn child as a "selfobject" that reflects and confirms (i.e., mirrors) her self-worth and represents (i.e., idealizes) the best part of herself. As Kohut (79, 80) frequently warned, it is crucial to regard narcissism not as a primitive form of object relatedness (i.e., a form of psychopathology) normatively replaced by mutual ties but as a separate line of development that is never relinquished, while it is susceptible, like object relations, to maturational transformations. Studying pregnancy highlights how a mother's narcissistic investment in her unborn child is normal, although the nature of that narcissistic tie may be more or less adaptive (just as it is with the object tie to the child as a separate person).

Many of the reactions to perinatal loss may be more clearly understood by applying a narcissistic orientation than by viewing the loss as solely that of an object (18, 34, 36, 56, 77). Furman (35) poignantly described how many of the usual responses to perinatal loss—the emptiness, low self-esteem, and unbearable helplessness—emanate from this loss of part of the self. Since a selfobject, by definition, is experienced as an extension of oneself over which one has complete control (78), we can better understand the profound helplessness so often voiced after perinatal loss and why this is so intolerable in light of the omnipotence that pregnancy is meant to secure.

The underlying shame and feeling of inferiority resulting from narcissistic injury are particularly painful, likened to the experience of amputation (35) or the frustration of brain-injured patients (80). The pervasive low self-esteem—sense of inadequacy, failure, and worthlessness—following perinatal loss is less convincingly explained by the process of mourning an object loss than by the consequences of narcissistic damage and the inability of the deceased child (i.e., selfobject) to support maternal self-esteem. LaRoche et al. (9) re-

ported that although measures of bereaved mothers' depression and mourning showed a statistically significant and positive association, the degree of mourning for the dead child could account for only about 20% of the extent of depression. Perhaps the multiple narcissistic assaults on the mother's self-esteem contribute more powerfully to her depression than does the loss of her baby as a distinct object. Common psychosomatic manifestations after pregnancy loss, especially the sense of inner emptiness, of unreality, and of hearing a baby, may be rooted not only in the usual depressive symptoms and the physiological residues of pregnancy but in the fragmented experience of the self and the similar somatic complaints expressed by those coping with narcissistic assault (78).

The insensitivity of professional caregivers, family, and friends to parents experiencing perinatal loss has already been well documented. However, the fury provoked by this lack of understanding by others may be better appreciated by recognizing how narcissistic rage (80) is ignited by such personal injuries. The maliciousness sometimes attributed to insensitive or indifferent others may be based not on the degree of actual meanness shown but on the narcissistic vulnerability of these bereaved parents to slights. This statement is not intended to excuse professional or familial insensitivity, or to suggest that it is necessarily a misperception, or to pathologize this narcissistic vulnerability. Rather, it highlights the importance of empathic communication with these parents and how they may experience genuine slights as frontal assaults. Not understanding and misinterpreting their pain becomes a fresh stab in an open narcissistic wound. The high rate of litigation against obstetricians is probably not due to the poorer performance or greater insensitivity of these physicians. Seeking vengeance in a lawsuit in the heat of narcissistic rage that may have been fueled by a callous professional attitude seems a more convincing explanation.

Kohut described how, in the psychoanalysis of chronic narcissistic character disturbance (78) and less pervasive narcissistic problems, which he later claimed permeated virtually all emotional problems (79), the therapist's empathic bond facilitates the slow process of building a reliable, internalized self structure that can now regulate self-esteem without depending as desperately on the selfobject transference. The typical regression to greater narcissistic vulnerability in response to loss may be repaired in an empathic bond in short-term psychotherapy (18). Quantitative evidence for the value of empathic understanding in promoting narcissistic recovery may be provided by Murray and Callan's report (12) of parents expressing significantly higher levels of self-esteem when they were satisfied with support received from hospital staff members. Perhaps Furman (35) said it best and most clearly: "For the professional person to tell the parents just to bear it is not enough; to be with them and to extend oneself in bearing it can do much more. It is this, in part, which makes the job of working with these parents so difficult" (p. 216).

IMPLICATIONS FOR RESEARCH

Although the multidimensional psychoanalytic model proposed here is based on a study of 20 bereaved mothers evaluated for or in psychotherapy (18), it may productively guide quantitative research on perinatal loss to test specific hypotheses. There is an increasing trend toward the use of regression equations based on a wide net of independent variables in attempting to predict a "pathological" outcome, without the application or evaluation of any guiding theoretical model (8, 10-12, 14, 15). While significant results are inevitably discovered and thoughtful conclusions sometimes drawn, rarely are they meaningfully organized into a conceptual framework. As investigators have repeatedly indicated (14, 22, 23), differing results among studies (e.g., the effects of previous losses and births, length of gestation, etc. on the impact of perinatal loss) may have been significantly influenced by widely varying methodology, such as what perinatal losses were assessed, the nature of the sample, and how long after the loss measures were administered. Most researchers adhere to the prevailing model of object loss, comfortably using measures of mourning designed for other bereavements such as the death of a spouse (8-10, 13) and thereby disregarding important developmental, narcissistic, and conflict-related effects of perinatal death that would go undetected by these limited measures.

The construction of measures specifically oriented to perinatal loss is encouraging. The Perinatal Grief Scale (14, 15) has distinguished three distinct factors: active grief, difficulty coping, and despair. While active grief seems to be associated with mourning an object loss (e.g., "I am grieving for the baby," "I can't avoid thinking about the baby," and "I very much miss the baby"), despair appears to index narcissistic damage, including low self-esteem (e.g., "The best part of me died with the baby," and "I feel worthless since he/she died"), psychosomatic symptoms ("I feel physically ill when I think of him/her"), and a sense of emptiness ("It's safer not to love," and "I try to laugh, but nothing seems funny anymore"). This work appears to illustrate nicely how mourning object loss and incurring narcissistic injury are relatively independent aspects of perinatal loss.

Many studies readily equate the expression of intense grief with inadequate coping or unresolved grief (8, 10, 16, 17), even as early as 8 weeks after the death (11), when such intense grieving is to be expected. This suggests how deeply ambivalent researchers are toward the normalcy of intense grief after perinatal loss. While this grieving is repeatedly regarded as typical and is encouraged by providing opportunities to see and hold the dead baby, when it is empirically studied, intense grief, even soon after the death, is often viewed as pathological! Lasker and Toedter (15) recently reported that their factors of difficulty coping and despair were more significantly associated with chronic emotional problems 2 years after the loss than was active grief, which convincingly argues against equating the intensity of grief with problems in recovering from perinatal loss. Al-

though Theut et al. (16, 17) clearly recognized the importance of narcissistic loss, their Perinatal Bereavement Scale unfortunately focuses almost exclusively on mourning object loss, with questions on the death of the baby rather than diminished self-esteem. Their results revealed more intense and prolonged grieving for a late-term loss than for a miscarriage, a frequently reported finding (23) that is not surprising in light of the increasing attachment to the unborn child as a separate person as pregnancy advances. Toedter and Lasker (14, 15) confirmed this expected finding, reporting that the gestational age of the unborn child was more strongly associated with active grief (i.e., mourning object loss) than with their other two factors.

While it will be a challenge to quantify intrapsychic variables, at least some measures of overall psychological functioning and coping are necessary, lest it be assumed (as some studies appear to do) that the impact of perinatal loss is solely determined by the circumstances of the loss and environmental factors (which, of course, are more readily assessed). Kellner et al. (81) have indicated that demographic and obstetric characteristics are in fact poor predictors of parental reactions and decisions after perinatal loss, a finding emphasized by Lasker and Toedter (15) in their consideration of long-term consequences. On the basis of their empirical investigation of perinatal loss, Smith and Borgers (13) similarly concluded that "it is not the particular variables of the loss experience which influence the grief response as much as the individual personality variables and the perception that the loss experience is not understood or supported by family and community" (p. 212). The different psychoanalytic models that I have outlined should be evaluated by measures of perinatal loss. The developmental model would predict that perinatal loss before a successful birth will generally be more difficult to endure—a recently reported finding by Lasker and Toedter (15)—because of the greater interference in development and isolation that these parents have to bear in comparison with those who have attained parenthood before such a loss.

Psychoanalytic studies of clinical subjects typically reveal that prior disturbance, unless treated, leads to maladaptive outcome in pregnancy (42, 82), and it seems reasonable to expect that this relationship would be at least as powerful under the additional stress of perinatal loss. Lasker and Toedter (15) in fact discovered that prior mental health problems were the most powerful predictor of enduring emotional problems 2 years after the loss. It is especially valuable not to rely on clinical studies that will be oriented to psychopathology but to consider psychoanalytic investigations that use untreated subjects, such as those conducted by Bal-lou (47) and Bibring (44, 45). Their subjects suggest an important resourcefulness and potential for new adaptation during pregnancy, without treatment or with limited supportive intervention, even among those struggling with prior conflicts. The individualized ways in which parents memorialize their deceased babies (18) illustrate the possibility of creative outcomes in the

mourning process, as described by Pollock (83, 84). Clinical case studies provide an in-depth perspective that is rarely available in research interviews, but they cannot replace untreated samples, which, while evaluated psychoanalytically, may be less susceptible to a bias toward pathology. In developing indexes of intrapsychic functioning, it will be important to consider ego strength as well as disturbance.

Research should assess more precisely the meaning of the pregnancy loss in light of the mother's history. While many studies report no significant association between prior losses and the impact of perinatal death (7, 10, 13-15, 54), no study has examined the possible relation between resolution of earlier losses and subsequent perinatal death, thereby obscuring the impact of earlier losses (12, 22). Furthermore, even if no significant effects on grieving are uncovered, this does *not* mean that earlier losses are inconsequential. In his richly illustrated nonquantitative study of pregnancy following a stillbirth, Phipps (85) described how mothers may typically guard against another feared loss by muffling their attachment to the next child during pregnancy and for some time after birth. More intense grief, which one might expect if an additional perinatal loss should occur, may thereby be avoided. In these instances, a previous perinatal loss may have a significant impact on the mother, albeit not detected by a simple quantitative scale of grieving over object loss.

The qualitative dimensions of depression evoked by perinatal loss must be more carefully distinguished as well as calibrated. It is no longer adequate to apply a global measurement of depression as indicative of unresolved grief; dimensions of grief are not effectively assessed by indexes of depression only (9, 14, 15). A certain degree of behavioral self-blame, in which the bereaved parent believes that future losses may be prevented by specific actions, may engender a sense of mastery and control, limiting the traumatic helplessness that often follows such a loss; this is suggested by empirical findings supporting the defensive-attribution hypothesis (86-88). This guilt, inoculating the bereaved against a more debilitating powerlessness, must be conceptually and methodologically distinguished from the feeling of worthlessness resulting from narcissistic damage, which, while common, is not adaptive. Very different questions would distinguish a mother blaming herself for behavior during her pregnancy that she could change in the future and a mother experiencing a pervasive sense of failure. There is also a crucial difference in affective tone; self-blame regarding behavior potentially provides hope and the possibility of efficacy for the future, while narcissistic devaluation intensifies despair and inadequacy.

Finally, the impact of perinatal loss on the father should be studied more carefully and distinguished along these dimensions. This article has focused on maternal reactions. However, fathers grieve after perinatal loss, although with reportedly less intense and sustained guilt and depression than do mothers (11-13, 16, 17, 32, 54). While the differing biological participa-

tion of men and women in pregnancy might suggest more profound object and narcissistic losses for mothers than fathers, this is subject to individual variation. Perinatal loss may be expected to precipitate developmental interference and revived conflicts in men, just as in women. The research literature may exaggerate how differently men and women respond to perinatal loss, obscuring how similar their coping reactions may be (89). I have dealt with the complicated dynamics of perinatal sibling loss elsewhere (18, 19, 90).

CONCLUSIONS

Over the past 20 years, we have come to appreciate that perinatal death usually means the death of a baby. We now need to consider more thoughtfully how this death has other implications as well for a parent's self-esteem, developmental goals, and ability to cope with earlier conflicts. A multidimensional psychoanalytic model can assess how perinatal loss causes developmental interference, intensifies chronic conflicts, presents particular challenges to mourning an object loss, and inflicts narcissistic damage. This multifaceted paradigm may help account for individual differences as well as explain the multiple effects of perinatal loss on the bereaved parents. Not only may this perspective improve the development of clinical interventions (18) but it may productively guide research—suggesting important and meaningful questions and providing a conceptual framework in which to interpret results and a means of testing and refining the theoretical system. Psychoanalytic insights and hypotheses should be more systematically used not only in the familiar terrain of case studies but in quantitative investigations of perinatal loss as well.

Contested Boundaries of Bipolar Disorder and the Limits of Categorical Diagnosis in Psychiatry

Deborah Blacker, M.D., Sc.D., and Ming T. Tsuang, M.D., Ph.D., D.Sc.

The authors' primary objective is to outline the phenomenology, importance, and available data on issues concerning the boundaries between bipolar disorder and diagnoses such as schizophrenia, unipolar depression, and personality disorders. In addition, by illuminating the many difficulties with the boundaries of one of psychiatry's more robust diagnoses, they hope to awaken in the reader a healthy skepticism about current psychiatric nosology. For a topic of this scope, a literature review must be selective. For each boundary area, a mixture of classic and recent papers covering a range of validating criteria is included whenever possible. Good summary data are cited when available, as are a selection of relevant theoretical papers. The review indicates that current diagnostic criteria for bipolar disorder are generally reasonable, but there are many problem areas, most of which cannot be solved by changes in criteria. Notable among these are 1) the possibility of future manic episodes in unipolar disorder, 2) schizoaffective disorder, bipolar type, and 3) borderline personality disorder with prominent mood swings. The disputes concerning the boundaries of bipolar disorder illustrate the limitations of categorical diagnosis which result from the implementation of diagnostic criteria, the criteria themselves, the fundamental nosologic process, and the phenomena themselves. If these limitations are to be extended, it may be necessary to explore alternative ways of defining psychiatric diagnoses for different settings in research and clinical practice.

(Am J Psychiatry 1992; 149:1473-1483)

Bipolar disorder, by virtue of its fairly distinct phenomenology, its occurrence throughout history (1) and across cultures (2), its patterns of inheritance (3), and its clear disturbance of physiologic function (4), can lay claim to being one of psychiatry's most robust diagnostic entities. Because the readily recognizable core phenomenology—episodic highs and lows and a normal baseline in between—may be absent or obscured by other symptoms, the diagnosis is often difficult to make in practice (5), even by using the relatively narrow and explicitly defined *DSM-III-R* criteria. Some of the ambiguity has to do with operationalizing the

criteria and is usually in the form of unreliability. Such issues, while critical (6), are generally beyond the scope of this essay. Our primary concern is the *validity* of the criteria, particularly as they distinguish bipolar disorder from other psychiatric syndromes.

We begin from the premise that there is a valid diagnostic entity called bipolar disorder, the center of which is well-defined and well-recognized. Clinical experience tells us that symptoms of bipolar disorder overlap substantially with those of other psychiatric disorders. As the patient becomes more psychotic, particularly as symptoms become more chronic, we wonder about schizophrenia. As manic symptoms become less prominent or are absent altogether, we wonder about unipolar disorder. If a substance-abusing patient has mood swings, we wonder if they are drug-induced or whether drugs are masking more dramatic affective episodes. As a framework for this discussion, we have chosen to think of each of these alternative diagnoses as defining a boundary of bipolar disorder, as represented in figure 1. We do not mean to imply that the alternative diagnoses do not overlap with one another, nor do we mean that individual patients can be mapped onto this diagram. Indeed, in the clinical setting, the most difficult patients tend to straddle several of these boundaries. However, most of the interesting nosologic questions *can* be mapped onto the diagram: bipolar II disorder on

Versions of this paper were presented at the Harvard Psychiatric Epidemiology Colloquium on March 20, 1991, and at Grand Rounds at the Psychiatry Service, Brockton VA Medical Center, and the Department of Psychiatry, Dartmouth Medical School. The paper was also presented in part at the 144th annual meeting of the American Psychiatric Association, New Orleans, May 11-16, 1991. Received Aug. 19, 1991; revision received Feb. 19, 1992; accepted March 6, 1992. From the Program in Psychiatric Epidemiology, Harvard School of Public Health and Harvard Medical School, Boston; the Department of Psychiatry, Harvard Medical School; Massachusetts General Hospital; and the Brockton VA Medical Center, Brockton, Mass. Address reprint requests to Dr. Blacker, MGH East, 9th Floor, Department of Psychiatry, Massachusetts General Hospital, Boston, MA 02114.

Supported in part by grants MH-17119, MH-46318, and MH-43518 (Merit Award to Dr. Tsuang) from NIMH and by a VA Medical Research Merit Review Grant.

FIGURE 1. The Boundaries of Bipolar Disorder

the boundary with unipolar illness, schizoaffective disorder on the boundary with schizophrenia, and so on.

Our primary aim is to review each of these boundary areas. After a brief description of a boundary's phenomenology and importance in practical and theoretical terms, we go on to review the available data and draw reasonable—sometimes tentative—conclusions. We have tried to cover a wide range of issues within the constraints of available space but have made depth of discussion a function of the importance of the issue in question. In choosing evidence, we have been guided by the standard validating criteria for psychiatric nosology outlined by Robins and Guze (7). However, we agree strongly with Kendler (8) that evidence from different validating criteria may be in conflict and that certain criteria may make more sense in certain settings.

We do not, in general, aim to suggest improvements in criteria for bipolar disorder in *DSM-IV*. No matter how we define criteria, considerable ambiguity about where and whether to draw lines between bipolar disorder and other disorders will remain. Many questions transcend the revision of diagnostic criteria; different criteria may be appropriate for different purposes (8), and some questions can only be answered probabilistically. Thus, we are concerned at a more theoretical level with how we can decide what should and should not be classified with bipolar disorder in a given setting.

These general issues point to our secondary aim. The boundary issues concerning bipolar disorder are by no means unique. Instead, they illustrate a broad range of critical theoretical issues for diagnostic boundaries. Indeed, diagnostic ambiguity is much more serious for many disorders defined in *DSM-III-R* and will no doubt remain so with the publication of *DSM-IV*. There are distinct limits to our ability to draw lines between disorders on the basis of phenomenology alone. At least for some psychiatric disorders, discrete categories may be an illusion. A number of papers have raised some of these concerns (8–11), yet few have done so in

the context of a specific diagnosis. By grounding our discussion in one of psychiatry's best-characterized disorders, we hope to underscore deeper difficulties with current psychiatric classification systems.

THE UNIPOLAR-BIPOLAR DISTINCTION

The phenomenology at the boundary between unipolar and bipolar disorder is one of nested symptoms; i.e., all of the symptoms of unipolar disorder are within the definition of bipolar disorder. Because anyone with unipolar disorder could go on to have a manic episode and be diagnosed retrospectively as bipolar from the first onset of depression, the diagnosis of unipolar disorder must be provisional, at least through the broad age range of susceptibility to mania. Given an episode of major depression, bipolar II disorder (depression plus hypomanic episodes) lies on a continuum with bipolar I disorder (for which manic episodes are required) and thus raises a different set of issues.

Ambiguities at this boundary are critical, in large part because unipolar disorder is vastly more prevalent than bipolar disorder. In addition, unipolar disorder is more difficult to distinguish from normal mood changes, and estimated prevalence rates vary widely depending on duration, severity, and the required number of symptoms (3). Also, unipolar disorder is clinically and probably etiologically more heterogeneous than bipolar disorder (12). Finally, the distinction is central to the current understanding of mood disorders.

The Current Boundary

Support for drawing a boundary between unipolar disorder and bipolar disorder is far too extensive to detail here. The distinction is validated to an extent by each of the classic criteria (7), but in all cases there is substantial overlap, which, as several investigators have pointed out, is equally compatible with continuum models (13, 14). It must be noted, however, that true differences are probably larger than those observed: because of the possibility of a later manic episode, samples of unipolar subjects inevitably contain some bipolar individuals.

Epidemiologic studies show consistent differences between unipolar and bipolar disorder in sex ratio, age at onset, and frequency of affective episodes (4). Depressive episodes in bipolar disorder appear to be more severe (15), even psychotic (16), and to have so-called reverse neurovegetative signs (17). Follow-up data suggest that between 5% and 20% of unipolar patients switch to a bipolar course (18–21).

The genetic data are equally complex; they have been summarized by Tsuang and Faraone (3). In general, bipolar disorder shows clearer genetic transmission than unipolar disorder. Only a few studies of the relatives of unipolar probands have shown a significantly greater prevalence of bipolar disorder than in the relatives of control probands, but most studies of the relatives of bipolar probands have shown a two- to threefold in-

crease in the prevalence of unipolar disorder (14, 22). The increase in unipolar disorder in the relatives of bipolar probands tends to diminish, however, if three or more episodes of depression are required for a diagnosis of unipolar disorder (3). However, evidence varies, as do interpretations, and there are not enough data to decide unequivocally between continuum and separate disorder models.

As for response to treatment, bipolar disorder appears to be more responsive to prophylactic lithium (23), but the differences may have been overstated (24, 25). Antidepressant treatment may be more likely to cause manic symptoms—or full-blown manic episodes—in bipolar patients (26), but this too is controversial (27, 28), and the reasoning can sometimes be circular, since some researchers use pharmacologically induced hypomania as a marker for bipolar disorder (20, 21).

There is some evidence that subjects with unipolar and bipolar disorder differ on a number of laboratory measures, such as neurotransmitter metabolites and neuroendocrine response (4). However, in addition to the lack of robust, replicable differences, much of this evidence suffers from failure of studies to distinguish between state and trait (comparing depression and mania rather than unipolar disorder and bipolar disorder) or to control for the effects of activity level, sex, age, and so on (13).

"Potential Bipolar" Individuals

What are sometimes called false unipolar individuals (3, 4)—those who currently have unipolar depression but will go on to have a manic episode—pose the most intractable difficulties on this boundary. No set of criteria can tell us which unipolar individuals should be considered bipolar for research or clinical purposes. Given a crystal ball, one could limit oneself to the 5%–20% who will actually manifest mania. Consistent with unipolar-bipolar differences, the highest rates are reported for younger (21) or more severely depressed (18) samples, although longer follow-up time (18) and less stringent criteria for mania (20) must also play a role. Similarly, the unipolar individuals who switch at follow-up are younger, include more males, and have more severe episodes, and they may have more prior episodes, earlier age at onset, and certain specific symptoms (20, 21, 29).

Data about these "switchers," however, tell us only about unipolar subjects who actually manifest mania; there must be individuals who share the bipolar genetic liability but for some reason (e.g., variable expressivity of a putative gene for bipolar disorder, absence of environmental or genetic cofactors, competing risks) never have a manic episode. This group is more theoretical and therefore cannot be clearly quantified, much less profiled. According to the most conservative definition, it is limited to those individuals who die (e.g., by committing suicide) during or after an episode of depression and before what would be their first manic episode. According to the most extreme definition, it could include

all unipolar individuals and therefore be equivalent to denying the unipolar-bipolar distinction.

However they are defined, "potential bipolar" individuals constitute some fraction of those diagnosed as having unipolar disorder. Failure to take this into account is probably responsible for at least some of the confusion besetting genetic, physiologic, and treatment studies of the unipolar-bipolar distinction. Some authors have suggested using family history of mania as a way to distinguish which unipolar individuals should be considered as potentially bipolar, and have even suggested that unipolar individuals with family histories of bipolar disorder be called bipolar III (12, 30). Using this criterion in conjunction with the observed characteristics of "switchers" may be of some help for clinicians' informal weighing and balancing, but it is unlikely to be adequate for most research purposes. Family history is particularly problematic within the context of genetic research, since unipolar disorder is so common that some relatives with unipolar disorder would be found in the families of bipolar probands by chance.

The Status of Bipolar II Disorder

Bipolar II disorder (classified in *DSM-III-R* within the category of bipolar disorder not otherwise specified) could be part of unipolar disorder or bipolar disorder, could represent a valid diagnosis in its own right, could be the midpoint on a continuum, or could simply be useful as a buffer zone. Studies of bipolar II disorder have been limited by variable definitions (31) and the well-documented difficulties in assessing hypomania (19).

The data on bipolar II disorder suggest that it is more similar to bipolar I disorder than to unipolar disorder in demographics and course of illness: there is a fairly early age at onset, males are represented more nearly equally, and episodes are more frequent, more severe, and more likely to have reverse neurovegetative signs (30, 31), but such findings are not universal (32). Family studies tend to show that bipolar II disorder is more like bipolar I (12, 31). However, the greater rate of bipolar II disorder in the families of probands with bipolar II disorder suggests that bipolar II may be, at least to an extent, a genetically separate syndrome (31). In addition, there is some evidence that bipolar II disorder is more likely than unipolar disorder or bipolar I disorder to occur with other psychiatric diagnoses, including personality disorders and substance abuse (31). This comorbidity, along with the inconsistencies in the other findings, may be an indication that bipolar II disorder is heterogeneous and includes some true bipolar individuals, some unipolar individuals with other problems that are easily confused with hypomanic episodes, and some individuals with multiple diagnoses.

SCHIZOPHRENIA VERSUS BIPOLAR DISORDER

The boundary between bipolar disorder and schizophrenia involves not a true continuum of purely quan-

titative changes but, rather, varying admixtures of features thought to cluster in one disorder or the other. Much of the dispute has centered on the definition and interpretation of schizoaffective disorder, a diagnosis for those patients whose psychotic symptoms are not clearly linked to their affective episodes. Fewer data are available for two other related disorders, schizophreniform disorder and brief reactive psychosis, so our discussion will concentrate on schizoaffective disorder.

Although the number of potentially misclassified patients is smaller here than at the boundary with unipolar disorder, it is large enough to pose significant practical problems. In addition, because the relation between cross-sectional symptoms and course of illness is critical to the modern understanding of bipolar disorder, this boundary is of great theoretical interest.

The Schizophrenia-Bipolar Split

Despite the similar demographic features, clinicians and investigators have no difficulty distinguishing the phenomenology of classic schizophrenia and classic bipolar disorder, particularly if they have access to longitudinal as well as cross-sectional information. Unlike schizophrenia, classic bipolar disorder is episodic, its episodes are marked by affective and neurovegetative changes, and its psychosis is linked temporally and thematically with mood (*DSM-III-R*). However, religious and paranoid delusions or hallucinations, catatonia, and incoherence can be seen in both disorders, and certain other features said to be typical of one or the other (*DSM-III-R*) involve very subtle distinctions—between inappropriate and labile affect, between flight of ideas and looseness of associations, and so on.

Of course, many patients do not present a classic picture; a substantial minority of patients are difficult to place on one side of the boundary or the other. The findings of Brockington et al. (33) are consistent with clinical experience: in their discriminant function analysis, a general psychotic sample conformed to a bimodal distribution, but, not surprisingly, a sample of schizoaffective patients did not. Some have argued that the very existence of patients with schizoaffective disorder is strong evidence for a continuum of psychotic disorders, or even a unitary psychosis (34), but the data are compatible with a number of other explanations.

On the whole, the distinction between bipolar disorder and schizophrenia appears stable over time. A few follow-up studies have found changes from schizophrenia to bipolar disorder, or vice versa, in a modest fraction of patients (35), but these may represent initial misdiagnosis due to overreliance on cross-sectional symptoms. As for the relation between cross-sectional symptoms and outcome, despite the classic descriptions, it is well-known that some schizophrenic patients do well (35, 36), and some bipolar patients develop chronic courses (37). Kendler et al. (38) raised the possibility that poor outcome is observed more frequently in schizophrenic patients simply because past chronicity (required for the diagnosis of schizophrenia) predicts

future chronicity, but they found in their review that course was fairly strongly associated with cross-sectional symptoms: 6 months of symptoms predicted a poor outcome *only* in patients with index symptoms of schizophrenia, not of bipolar disorder.

Family data tend to support separate inheritance: each of the classically defined disorders "breeds true" to a substantial extent (3, 4). Only small increases in bipolar disorder—usually not statistically significant—are reported among the relatives of schizophrenic subjects when they are compared to relatives of control subjects (22, 39, 40), and the same is true for schizophrenia among the relatives of bipolar subjects (14, 22, 41). This very modest "heterotypic risk" may be consistent with classification error, as demonstrated by Kendler (42).

Fairly robust differences in response to treatment have been observed. Lithium is not generally helpful for patients with schizophrenia, while it decreases the severity and duration of individual episodes and is prophylactic against further episodes in patients with bipolar disorder (43). Of course, both disorders (and many others with psychotic features) tend to respond to neuroleptics, but this is rarely used as an argument for the unity of psychotic disorders.

Physiologic and anatomic data on the two disorders as classically defined do show some differences, but none is robust enough to serve as a biological marker. Structural abnormalities are more frequently reported in schizophrenic individuals, but they have also been found in many bipolar subjects (4). Functional abnormalities, including changes in sleep architecture, endocrine responsiveness, and catecholamine metabolites, are more easily demonstrated for bipolar disorder (4). However, it is difficult to know to what extent these are simply the physiologic manifestations (state markers) of increases in activity in the manic state.

On the whole, there is considerable support for the clinical and research utility of separating bipolar disorder and schizophrenia. Although the unitary psychosis model is difficult to disprove, the differences observed—despite dilution due to at least some misclassification—and the fairly low prevalence of schizoaffective disorder compared to bipolar disorder and schizophrenia lend support to the two-major-psychoses model. Especially in the complex boundary zone, however, much work remains to be done.

What Is Schizoaffective Disorder?

Like bipolar II disorder, the schizoaffective diagnosis was created as a buffer zone, and similar questions apply. Studies of schizoaffective disorder must be read and compared with particular care, since the term has been used with a variety of meanings. The Research Diagnostic Criteria (RDC) subtyped schizoaffective disorder on the basis of mania versus depression and mainly affective (mood-incongruent psychosis *within* a mood episode) versus mainly schizophrenic (psychosis *between* episodes) (44, 45). Although not everyone agrees

(46), these distinctions appear to make a difference. First, schizoaffective depression may be more common (45) and appears to differ more from the corresponding mood syndrome than does schizoaffective mania, especially within the mainly affective subtype (47–49). The mainly affective subtype appears to be more similar to mood syndromes, especially within the manic or bipolar group (40, 47–49). Because several studies found RDC-defined schizoaffective mania to be virtually indistinguishable from bipolar disorder on a number of validating criteria (at least in the mainly affective subgroup, which probably predominated in these studies) (47, 48), the *DSM-III* criteria for mania were broadened to allow more psychosis within individual episodes. Although this change has remained somewhat controversial, the similar changes made for depression are far more problematic (35, 45).

We have tried to limit the discussion to studies that have reported specific information on *DSM-III-R* schizoaffective disorder, bipolar type (or the nearly equivalent RDC mainly schizophrenic subtype of schizoaffective mania). However, because narrowly defined schizoaffective disorder as a whole is fairly uncommon, such studies are quite rare. As would be expected from the diagnostic criteria, schizoaffective disorder, bipolar type, has a course and outcome between those of bipolar disorder and schizophrenia (35). Family studies are perhaps the most confusing and the least likely to report separate data. In general, modest increases in bipolar disorder are seen in the families of individuals with schizoaffective disorder, bipolar type, but there are more substantial increases in schizophrenia in these families (40). Few studies have found increases in schizoaffective disorder, bipolar type, itself in the families of probands with the disorder, and thus there is little support for the separate disorder model (49, 50). Studies of response to treatment suggest that lithium may help some patients with schizoaffective disorder, bipolar type, but probably not to the extent that it helps patients with bipolar disorder (50). Of course, lithium's specificity may be for affective (particularly manic) symptoms rather than for bipolar disorder per se. Physiologic studies have found no differences that consistently separate schizoaffective disorder from bipolar disorder or schizophrenia (49).

Given the paucity of specific data, it is no surprise that investigators have been unable to reach consensus on the status of schizoaffective disorder, bipolar type (4, 51). Under these circumstances, it seems wise to maintain schizoaffective disorder, bipolar type, as a buffer zone. As a disorder in its own right, it has little a priori appeal, and almost no data support it. As Levitt and Tsuang have argued (50), schizoaffective disorder is likely to be quite heterogeneous. Schizoaffective disorder, bipolar type, probably includes some individuals who belong in one of the adjacent categories, but it may also include many individuals with organic or other as-yet unrecognized psychotic disorders that do not fit the picture of bipolar disorder or schizophrenia. We may be able to refine the diagnosis of schizoaffective

disorder, bipolar type, by pooling data from older studies and exploring which subtyping schemes are predictive of differences in outcome, treatment, and familial relationships.

CYCLOTHYMIA

The boundary of bipolar disorder with cyclothymia—the term is used here to denote formal *DSM-III-R* cyclothymia along with any other syndrome made up of minor highs and lows—is on a true continuum with bipolar I disorder and bipolar II disorder. Cyclothymia is rarely defined specifically; rather, it refers to a syndrome made up of episodes resembling depression and mania but of insufficient severity, duration, or number of symptoms to meet the criteria (*DSM-III*, *DSM-III-R*, 52). Thus, it is by definition, if not in fact, a mild form of bipolar disorder. While *DSM-III* and *DSM-III-R* add a chronicity requirement (no more than 2 months at a time can be symptom free), this definition has not been applied consistently in the literature.

Understanding the relation of cyclothymia to bipolar disorder has considerable practical implications, since the syndrome appears to be at least as common as bipolar disorder. In addition, because cyclothymia exists on a continuum with bipolar disorder at its upper boundary and with normal mood swings at its lower boundary, it may contribute to an understanding of some of the positive aspects of bipolar disorder and related phenomena (4).

While the nature of cyclothymia's relation to bipolar disorder remains unclear, the fact of a relationship seems well-established. By definition, the phenomenology is closely linked. Mood swings per se may not be unique to bipolar and related disorders, since Fichtner et al. (53) found them as often in schizophrenic as in bipolar individuals. Nonetheless, cyclothymia itself does cluster with bipolar disorder and not with schizophrenia. Clinicians frequently note that many patients with bipolar disorder have a history of antecedent cyclothymia, and Akiskal et al. (52) confirmed this on a prospective basis in a group of outpatients with cyclothymia. With the exception of Andreasen et al. (47), who reported very low rates of cyclothymia in relatives of probands with all subtypes of affective disorder, nearly all family studies support a relationship between cyclothymia and bipolar disorder. Bipolar disorder is increased in the relatives of cyclothymic patients (52) and cyclothymia in the relatives of bipolar patients (14, 41, 54). There are also a few reports of decreased mood swings when cyclothymic patients are treated with lithium (43, 52). In addition, Akiskal et al. (52) reported a substantial incidence of hypomania in cyclothymic patients during treatment with antidepressants.

There seems to be little doubt that at least some fraction of cyclothymic individuals should be considered to have a variant of bipolar disorder, at least for some purposes. However, particularly if very lax criteria are used, a number of patients with normal mood swings or con-

ditions mimicking hypomania may be included inadvertently. Impairment or hospitalization makes sense as a cutoff point between the diagnoses in clinical settings but not necessarily elsewhere. There is no evidence that the chronicity requirement in *DSM-III-R* helps to distinguish the fraction of cyclothymia related to bipolar disorder (either by outcome or familial connection) from a more generic type. If suitable numbers of subjects could be found, research aimed at elucidating which characteristics predict a relation to bipolar disorder would be most helpful.

PERSONALITY DISORDERS

The boundary of bipolar disorder with personality disorders concerns *DSM-III-R* cluster B, including especially borderline but also histrionic and narcissistic personality disorders. The phenomenology is one of overlapping symptoms. Borderline personality disorder shares affective instability, impulsivity, and transient psychosis with bipolar disorder; histrionic personality disorder shares flamboyance, emotional shifts, and low tolerance of frustration; and narcissistic personality disorder shares grandiosity (*DSM-III-R*). Furthermore, as *DSM-III-R* notes, the boundaries of personality disorders themselves are not very clear; individuals often have features of more than one personality disorder (especially within the same cluster), which only makes the differential diagnosis with affective disorders more difficult. Co-occurrence of personality and affective disorders, possibly including bipolar disorder, raises additional concerns at this boundary.

In addition to the impact of the issue on clinical practice, the relation between personality and affective disorders has profound implications for our understanding of the axis I versus axis II model in our diagnostic system. Despite the atheoretical stance of *DSM-III-R*, there is a tendency to view affective syndromes as being biological or genetic in origin and personality syndromes as being interpersonal or historical in origin, while the truth is probably far more complex. For instance, cyclothymic, hyperthymic, and dysthymic temperaments (which were formerly classified as personality disorders) clearly are related to both mood syndromes and personality.

Despite the intense clinical and research interest, there are only limited data about the relation between personality disorders and bipolar disorder, and they mostly concern borderline personality disorder. There is evidence for increased major depression in borderline patients, and Akiskal et al. (55) have reported increases in bipolar II disorder and cyclothymia as well. In addition to co-occurrence, there may be a "switch" to a diagnosis of mania or hypomania in some individuals initially diagnosed as having borderline personality disorder (55). Family data are unclear. While Akiskal et al. (55) reported some increase in bipolar disorder among relatives of borderline patients, Pope et al. (56) saw increases in depression only, and these may be clustered

in the relatives of borderline patients who themselves have affective disorders. Rates of borderline personality disorder are not reported in most family studies of affective disorders (14, 22, 41, 47, 54), but Coryell and Zimmerman (57) did not see significant increases in borderline or other cluster B personality disorders in relatives of patients with major depression. While there are anecdotal reports of borderline patients improving with either carbamazepine (58) or lithium (59), it is difficult to support a relationship on this basis.

DSM-III and *DSM-III-R* draw a clear boundary between mood disorders on axis I and personality disorders marked by mood *instability* on axis II. Akiskal and colleagues (55, 59) have proposed blurring this boundary, at least for borderline personality, and argue that a substantial fraction of patients diagnosed as borderline may have an alternative form of bipolar disorder. Available data do not offer strong support for either of these extreme positions and are consistent with a variety of more complex relationships between personality and affective disorders, as outlined elsewhere by Akiskal et al. (60). Personality disorders may simply mimic bipolar disorder, especially when they coexist with substance abuse (see below). They may also contribute to the development of bipolar disorder by unmasking latent symptoms. In addition, character disorders could in some cases result from developmental factors associated with growing up with bipolar disorder itself, with the liability to bipolar disorder, or with affected parents. Last, personality disorders may be modifiers of course, severity, or outcome.

The current division between affective and personality disorders may remain clinically useful in separating what appear to be state phenomena associated with affective episodes from trait phenomena associated with character pathology, but the substantial overlap between these phenomena make it quite problematic. A clearer picture of this complex area must await more family and outcome data on the relation of bipolar disorder to borderline and other personality disorders.

SUBSTANCE ABUSE

Concerns about an association between substance abuse and bipolar disorder are largely related to their frequent co-occurrence in the same individuals. In addition, there are overlapping symptoms related to intoxication and withdrawal of CNS stimulants and depressants and disparate symptoms related to abuse and dependency per se. The boundary is important because substance abuse and dependence are quite common and entail substantial morbidity and mortality. Understanding the relationship could improve treatment of both disorders and might help prevent the poor outcomes associated with comorbidity. In addition, misdiagnosis due to mimicry and masking may mar genetic and other research efforts.

There is substantial evidence for co-occurrence of bipolar disorder and substance abuse. Extensive comor-

bidity has long been reported in both clinical and population studies, including the Epidemiologic Catchment Area study (61). Several studies support the clinical wisdom that drinking is probably concentrated in the manic phase (62, 63). There is little support from family data for any shared etiology, although a recent study (George Winokur, personal communication) may call into question the prevailing wisdom that the greater alcoholism in families of bipolar probands is limited to relatives of *alcoholic* bipolar probands (4, 62, 64).

Bipolar disorder seems to be a risk factor for substance use and abuse, whether as self-medication (63) or simply because of impulsivity during the manic phase, but so far there are few data to support considering alcohol abuse as a variant of bipolar disorder. It is, however, important to be aware that affective syndromes may be difficult to diagnose in substance abusers and that one must consider both false negatives due to masking—especially of hypomania—and false positives due to mimicry, a particular concern with cocaine.

CHILDHOOD SYNDROMES

Critical issues for bipolar disorder's relation to childhood disorders include not only mania and depression of childhood onset but also attention deficit hyperactivity disorder. An understanding of these relationships could contribute to a developmental understanding of bipolar disorder.

It appears clear that adolescent-onset mania—which may be misdiagnosed as schizophrenia due to its more severe and bizarre presentation (65), but shows a long-term course similar to that of bipolar disorder (66)—is part of bipolar disorder. As for the much rarer childhood-onset variant, the relationship is less certain, and adequate follow-up and family data are lacking. Case reports, along with data from studies of children at risk, tend to support a relationship based on course of illness, family relationships, and response to treatment, but sample sizes are far too small to draw a firm conclusion (67–70).

The relation of childhood and adolescent depression to bipolar disorder is still less certain, but the association of earlier age at onset with increased switching from unipolar disorder to bipolar disorder raises a concern (21, 71). Family data are consistent with but not indicative of a relationship, perhaps due to small samples (69, 70, 72). While a larger fraction of childhood (and/or adolescent) than adult depression may be related to bipolar disorder, it would be inappropriate to conclude that childhood depression is a variant of bipolar disorder.

The relation of bipolar disorder to attention deficit hyperactivity disorder is in some ways the most intriguing (the term “attention deficit hyperactivity disorder” is used here, but many studies use *DSM-III* “attention deficit disorder with hyperactivity” or older diagnostic categories). The phenomenology involves overlapping symptoms, including distractibility, hyperactivity, and

impulsivity. Extensive data confirm the co-occurrence of attention deficit hyperactivity disorder with depression, and there are some suggestions for co-occurrence with bipolar disorder as well (73). Follow-up data are less revealing. While there are a number of case reports of a “switch” from attention deficit hyperactivity disorder to bipolar disorder (74, 75), the largest follow-up study (76) did not show increases in affective disorders among 18-year-olds with histories of attention deficit hyperactivity disorder. Family data are interesting but preliminary. There are clear increases in depression among the relatives of children with attention deficit hyperactivity disorder, even if the probands are not depressed (77). The same studies have found specific increases in mania, although none of these was statistically significant. As with depression, data from studies of children at risk have been equivocal, possibly due to sample size considerations (69, 70). It seems fair to conclude that much is suggestive of a possible relation between attention deficit hyperactivity disorder and bipolar disorder, but data are quite sparse. The existing data are consistent with explanations such as mimicry (or misclassification), prodrome, shared etiology, or chance. In any case, the relationship seems unlikely to apply to more than a small fraction of children with attention deficit hyperactivity disorder.

SECONDARY MANIA

The boundary of bipolar disorder and organic affective syndromes hinges on the issue of secondary *mania*, the sine qua non of bipolar disorder. There are several areas of concern, including endocrine, pharmacologic, and structural factors. While the numbers are fairly small, there is always a concern about misdiagnosing cases of secondary mania as bipolar disorder (78). In addition, the issue is important because of its vast potential impact on our understanding of disease process and etiology. Because the area is very broad and the data are fairly limited, the relevant issues can only be touched on.

The possible role of endocrine factors in bipolar disorder is in some ways the most interesting. Because of its strong effects on cognitive, motor, and appetitive functions, bipolar disorder reads as an endocrine disorder. While abnormalities of multiple endocrine systems are frequently reported, they tend to be highly inconsistent (79). A number of provocative observations suggest roles for corticosteroid, thyroid, and reproductive hormones, but despite extensive searches, no explanation for the pathophysiology of mania has emerged from endocrine studies (4).

Most of the pharmacologic agents that mimic or precipitate mania are stimulants and antidepressants, but there are multiple case reports and reports on series of patients regarding other agents as well (4, 80). The role of stimulants and L-dopa has drawn attention because of the interest in biogenic amines and affective disorders (4). The role of antidepressants, discussed above, has

also been related to the biogenic amine hypothesis and raises several clinical and theoretical concerns as well.

Studies of mania related to changes in brain structure have been less revealing (4). Despite multiple reported cases of mania following various head injuries and strokes (81), no consistent localizing findings have emerged, although there is a suggestion of a predominance of right-side lesions (82). However, substantial rates of abnormalities of the ventricles (4, 83) and of subcortical white matter (83, 84) have been reported in bipolar subjects and may represent an as-yet unidentified cause of secondary mania or simply a risk factor for typical bipolar disorder.

DISCUSSION

The many ambiguities in the delineation of bipolar disorder, a well-defined diagnosis supported by a considerable accumulation of data, should serve as a strong warning against any false reassurance proffered by apparently unambiguous *DSM-III-R* criteria. A range of complex and interacting issues contribute to the difficulties with our diagnostic system. We can view these difficulties as resulting from the implementation of the criteria (diagnostic reliability), the criteria themselves (diagnostic validity), the fundamental nosologic process, and aspects of the phenomena themselves.

Interpreting the results of research on diagnostic boundaries leaves us critically dependent on diagnostic reliability precisely where it is most questionable. The more a "boundary" represents a true continuum or overlapping symptoms, the less reliably can patients whose symptoms fall close to the line be diagnosed. Drawing on the example of bipolar disorder and schizophrenia, Kendler (42) demonstrated the perils of misclassification in family studies (where it is a particular problem because of the relatively poor quality of diagnostic evaluations of relatives), but no study of response to treatment, course of illness, or biological markers is immune. Thus, any conclusions about how each of two disorders with overlapping symptoms seems to be only partially responsive to a treatment thought specific for the other, or how an intermediate mean age at onset is observed for a disorder that forms a boundary between two other diagnoses, must be taken with a grain of salt. Such data are often equally compatible with the idea of truly separate disorders that are unreliably distinguished.

A critical issue for diagnostic validity is the choice of validators. A preference for etiologically defined disorders (9, 10) may encourage reliance on family and related studies to validate criteria for bipolar disorder, for which genetic factors are the most identifiable etiologic agents. For other disorders, there may be no reason to favor genetic validators, and we should be open-minded about what will prove the most useful in the long run. Even for bipolar disorder, the knowledge that all validators do not necessarily agree on the best set of criteria (8) should temper the emphasis on genetic validators. For instance, recurrent unipolar disorder ap-

pears to be more lithium-responsive (24), but family studies suggest that patients with three unipolar episodes are *less* likely to have relatives with bipolar disorder than those with a single episode (3). Treatment-response validators are quite problematic for making etiologic diagnoses (9) but may be best when determining criteria for clinical decision making.

Another critical issue is the trade-off between sensitivity and specificity, especially when we are interested in drawing lines between disorders lying along a continuum (e.g., bipolar disorder and cyclothymia) or with overlapping symptoms (e.g., bipolar disorder and schizophrenia). In some settings, it makes sense to maximize specificity and limit ourselves to more severe or more classic forms. In others, it may be more important to maximize sensitivity, and tolerate some individuals whose underlying disorder may be different, in order to capture everyone who is "truly" bipolar. At times, we may even want to cast a net as wide as the very inclusive bipolar spectrum proposed by Akiskal and colleagues (59, 85). Receiver operating characteristic analysis (86), which plots the sensitivity and specificity of a diagnostic test (e.g., a set of criteria) as a function of the cutoff (e.g., in number of symptoms or severity) for a positive result, can be used to compare the available information in different tests or to help tailor the cutoff value to the needs of a given setting.

In *DSM-III-R*, we have chosen a multiaxial system that is categorical rather than scaled and binary rather than probabilistic. The multiaxial system is at its best in distinguishing trait from state, such as personality traits (or disorders) from episodic ailments like bipolar disorder, but, as demonstrated here, it remains quite problematic. The remaining features of the system are modeled on medical nosology. Unfortunately, psychiatry's understanding is far behind its nosologic standards at the present time and may never catch up (9). At least at this stage of our development as a field, scaled or probabilistic alternative systems may offer certain advantages.

A categorical system has innate appeal but makes only limited sense when one is dealing with a true continuum such as mania and hypomania. Scales would facilitate the use of different cutoffs in different settings and would also allow psychiatrists to rate individual patients on separate dimensions (9, 10). For instance, at the boundary of bipolar disorder and schizophrenia, psychosis, chronicity, impairment, and affective symptoms may not sort together, and ratings on each of these dimensions might be more descriptive than labels such as schizophrenia, bipolar disorder, and schizoaffective disorder, bipolar type.

Similarly, a *binary* categorical system, in which the patient either has the disorder in question or does not, also has intuitive appeal, but a probabilistic system might have more utility. Clinicians use unspoken probabilistic systems quite frequently. They may pursue an organic workup more vigorously the less the picture resembles classic bipolar disorder, or prescribe antidepressants more carefully the more a unipolar pa-

tient has bipolar features or bipolar relatives. In research settings, a more formalized probabilistic diagnosis could prove quite useful indeed. For instance, a probability scale for certainty of diagnosis could be based on how thoroughly relatives have been evaluated in a family study or how closely they match the classic form of the diagnosis. Such probability scales have also been proposed as weighting schemes, for instance, weights based on the probability of underlying bipolar disorder among unipolar relatives in a linkage study (87).

Underlying all of these boundary problems is the fact that mental illness may not be a jointed creature, easily divisible into its component parts (8, 9). The substantial comorbidity of bipolar disorder and personality disorders may be an artifact of drawing an artificial line between two parts of an illness with a shared etiology. Another artifact may be our creation of boundary disorders such as bipolar II disorder and schizoaffective disorder. These may benefit research efforts by creating more homogeneous categories. Nonetheless, differences between the boundary disorder and the categories on either side support neither the validity of those adjacent categories nor, in general, the validity of the boundary disorder itself.

CONCLUSIONS

One of the problems with *DSM-III-R* is that it tries to be all things to all people. It is meant to be used for treatment decisions, billing, courtrooms, epidemiologic research, clinical trials, genetic linkage studies, and so on. In reality, each of these settings has different goals and therefore different needs, and the best way to satisfy these needs may be different for different diagnostic groups as well. While a classification system that suits everyone's needs and conforms to the same structure across a broad range of conditions appears to be a laudable goal, it may not be achievable, and its pursuit entails compromises that might, in the long run, cause more problems than they solve.

Under these circumstances, how shall we proceed? We surely cannot discard the gains that formal diagnostic criteria have brought us over the last 20 years. Without the current categorical system, most of the research findings used here to discuss its limitations would not be available. Instead, we must maintain our awareness of these limitations and take steps to overcome them whenever possible. This can best be accomplished by being more flexible in our diagnostic thinking and more innovative in our diagnostic practice. In future versions of the diagnostic manual—if not in *DSM-IV*, then in *DSM-V*—we may wish to consider following the lead of *ICD-10* (88) and coordinating *guidelines* for clinical practice with more explicit *criteria* for research. Beyond this, we may need to develop different sets of criteria for different research purposes, such as clinical trials, linkage studies, and so on. To describe better certain clinical phenomena or to suit particular clinical or research goals, we may need to

abandon simple categorical diagnosis altogether. We have discussed the potential advantages of receiver operating characteristic analysis, scaled or dimensional approaches, and probabilistic diagnosis. Many other options remain to be explored.

At least for bipolar disorder, existing diagnostic criteria may represent the best that can be achieved by using current methods of case definition, but they may not be adequate for a number of research and clinical purposes. As information accumulates on other disorders and diagnostic criteria are refined, similar limits will be reached. If we are to continue our progress toward improved understanding and treatment of bipolar disorder and other psychiatric illnesses, we must begin now to develop the nosologic techniques of the coming century.

Impact of Psychiatric Hospitalization on Behavioral Complications of Alzheimer's Disease

George S. Zubenko, M.D., Ph.D., Jules Rosen, M.D., Robert A. Sweet, M.D.,
Benoit H. Mulsant, M.D., and A. Hind Rifai, M.D.

Objective: The authors conducted a prospective study of the clinical utility of the four DSM-III-R subtypes of primary degenerative dementia of the Alzheimer type (with delirium, with delusions, with depression, or uncomplicated) and acute psychiatric hospitalization for treatment of these subtypes. **Method:** The subjects were 120 consecutive inpatients with Alzheimer's disease, most of whom had behavioral abnormalities. Each subject received detailed physical, neurological, psychiatric, and mental status examinations. The presence or absence of specific behavioral problems was also documented. Patients were treated with medication, psychotherapy, and behavioral techniques. **Results:** While all patients could be assigned to one of the four DSM-III-R behavioral subtypes, the uncomplicated subtype did not accurately reflect the burden of behavioral symptoms in the patients who did not have delirium, delusions, or depression. Each behavioral subtype responded in a characteristic way to inpatient treatment, as reflected by changes in scores on four psychometric scales used to assess cognitive impairment, psychiatric symptom severity, and level of functioning at admission and at discharge, as well as by changes in residential setting following hospitalization. Half of all patients admitted from their homes and two-thirds of those with depression were able to go home following discharge. **Conclusions:** Behavioral syndromes in Alzheimer's disease should not be overlooked, because they have both clinical and prognostic significance. Short-term psychiatric hospitalization is effective and efficient for achieving the goal of returning patients to their homes and for safely implementing specific treatments in this frail population, and it may reduce the need for institutionalization.

(Am J Psychiatry 1992; 149:1484-1491)

Primary degenerative dementia of the Alzheimer type (Alzheimer's disease) is characterized by progressive, global cognitive decline. However, aside from

this cardinal feature, there is remarkable individual variability in the age at onset of dementia (1-5), rate of cognitive decline (2, 6-8), presence of extrapyramidal symptoms (2, 9-14), and particular behavioral abnormalities that emerge (14-19). Estimates of the prevalence of behavioral complications in Alzheimer's disease have varied widely depending on the symptom or syndrome of interest, the clinical population studied, and the method used (18). Most estimates of the prevalence of psychosis (delusions or hallucinations) in Alzheimer's disease, obtained from cross-sectional studies of patients in diverse clinical settings, have been in the range of 28%-38% (18). However, longitudinal studies of clinically diagnosed or autopsy-confirmed cases

Received Oct. 16, 1991; revision received March 23, 1992; accepted April 2, 1992. of Alzheimer's disease suggest that the prevalence of psychosis may approach 50% by the time of death (14, 17). Similarly, most estimates of the prevalence of depressive disorders in demented outpatients with Alzheimer's disease have been in the range of 10%–25% (18). Both psychosis and major depression confer substantially greater morbidity and worse prognoses upon the demented patients who develop those complications (14, 16, 17). Patients with Alzheimer's disease are also at risk for developing delirium in response to a variety of extrinsic and intrinsic factors (20–22). Like psychosis and major depression, delirium is a potentially reversible condition that may be overlooked in demented patients, markedly reduces functional ability, complicates clinical management, and may terminate in death if the underlying cause is not corrected (20–24).

Unfortunately, there is no known means of preventing Alzheimer's disease, and no effective treatment for ameliorating the symptoms of cognitive impairment or slowing their progression has yet been identified. However, the behavioral symptoms and syndromes that often complicate the treatment of patients with Alzheimer's disease and that typically lead to placements in more highly structured, more expensive, and more restrictive settings are potentially remediable. In controlled studies, neuroleptic drugs have been superior to placebo in reducing the psychotic symptoms of patients with Alzheimer's disease (25). Neuroleptic agents have also been widely used for the nonspecific behavioral management of demented patients, although they may not be more effective in this regard than nonneuroleptic sedatives that lack motor and anticholinergic side effects (25–27). Several reports have suggested that the somatic treatments used to treat major depression in cognitively intact elderly patients—including tricyclic antidepressants (28–30), monoamine oxidase inhibitors (28, 31, 32), and ECT (33)—may also be effective in treating major depression in patients with Alzheimer's disease. Furthermore, controlled studies have supported the use of nonpharmacologic treatments for behavioral symptoms and syndromes in these patients. Finally, educational counseling and the supportive treatment of patients' families can ease the burden of caregiving (34).

Inpatient management of the behavioral complications of Alzheimer's disease provides an opportunity to make a thorough, multidisciplinary diagnostic and functional assessment after the discontinuation of all nonessential medications. In addition to ameliorating drug-induced behavioral abnormalities, this approach also provides a safe means of initiating treatment and carefully titrating doses of psychotropic medication to minimize side effects in this frail population. In our prospective study, we assessed the clinical utility of the four behavioral subtypes of primary degenerative dementia of the Alzheimer type described in *DSM-III-R* (with delirium, with delusions, with depression, and uncomplicated) and their response to short-term psychiatric hospitalization. The investigation was approved by the Institutional Review Board of the University of Pittsburgh.

METHOD

A total of 500 patients with late-life mental disorders were admitted to the geriatric clinical research unit at our hospital from Aug. 31, 1989, to March 15, 1991. A complete history of each patient was taken, and each underwent a physical examination and detailed neurological, psychiatric, and mental status examinations, with laboratory testing and brain imaging as previously described (7, 14, 35, 36). Medical problems were coded according to the *ICD-9-CM* system, with the exception that mental disorders and diseases of the brain were not counted. Psychiatric diagnoses were established according to *DSM-III-R* criteria with the use of information provided by the patient, his or her caregivers and outpatient physicians, and medical records to augment the results of the diagnostic evaluation performed on the unit. The diagnostic criteria of *DSM-III-R* were applied at a consensus conference attended by faculty psychiatrists (including each patient's attending psychiatrist), one of whom was also board-certified in internal medicine, and by research staff members, all with specialized expertise in geriatric psychiatry. Consensus opinions based on all available clinical, historical, and laboratory data were used to differentiate symptoms related to psychiatric syndromes from those attributable to concurrent primary medical illnesses. Of the 500 patients, 120 met the *DSM-III-R* criteria for primary degenerative dementia of the Alzheimer type and were included in the current study. These 120 patients would also meet the criteria of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association for possible or probable Alzheimer's disease (37). The clinical diagnoses of Alzheimer's disease made at our center with the use of similar criteria have been confirmed in approximately 85% of cases that have been autopsied (38).

The patient's behavioral subtype of primary degenerative dementia of the Alzheimer type described in *DSM-III-R*, the presence of other specific behavioral problems, and the age at first onset of dementia were also discussed at the consensus conference and recorded. For the diagnosis of the subtypes with delirium and with depression, the *DSM-III-R* criteria for delirium and major depression were used. The use of the criteria for major depression in the context of primary dementia has been validated by both neuropathological and neurochemical studies of post-mortem brain tissue (16, 39). Delusions were defined as described in *DSM-III-R*. Confabulations and misidentifications were not considered delusions unless they persisted in the face of incontrovertible evidence to the contrary. The patients who did not fulfill the criteria for any of these three subtypes were described as having the uncomplicated subtype, since no other category for primary degenerative dementia of the Alzheimer type exists in *DSM-III-R*.

We also documented the presence or absence of a group of specific behavioral problems, including hallucinations, irritability, aggression, restlessness, wander-

ing, abnormal verbalization, and any other behavioral problem during hospitalization that was judged to compromise significantly a patient's ability to care for himself or herself or to be cared for by others. These behavioral problems were recorded with a checklist that was completed for all patients with dementia. Like delusions, hallucinations were defined as described in *DSM-III-R*. Irritability was defined as a dysphoric state, often experienced subjectively as anger, during which there was an inappropriate threshold for the perception of stimuli as unpleasant or intrusive. Aggression was defined as the threat or commission of physical violence directed toward others or the intentional destruction of property. Restlessness was characterized as an abnormally increased level of motor activity. Wandering was defined as purposeless ambulation, often into socially inappropriate or potentially dangerous places. Abnormal vocalization was characterized as repetitive, stereotypical, or overly loud utterances that were socially inappropriate or disruptive to others. The consensus group also had the opportunity to record any additional behavioral abnormalities that substantially complicated the clinical presentation but were not captured by any of the other behavioral descriptors. Incontinence was not characterized as a behavioral abnormality because it often had multiple causes (e.g., medications, physical disability, infection), rather than being attributable to dementia itself, and because it could not be assessed in patients with urinary catheters. Best estimates of onset of symptoms were reached from historical information provided by the patients, family members, caregivers, and all other available ancillary sources.

The severity of cognitive impairment and behavioral symptoms was rated from information obtained during the first and last 72 hours of hospitalization. This information was reflected by four psychometric scales administered by one to three trained raters who were not involved in the clinical management of the patients. The Mini-Mental State examination, an 11-item series of interviewer-administered cognitive tasks (0=worst score, 30=best score) was used because it provides a reliable and valid index of cognitive impairment in the elderly (40). The severity of depressive symptoms was assessed with the 17-item Hamilton Rating Scale for Depression (41), which has scores ranging from 0 (best) to 52 (worst). While there is some overlap in the symptoms scored by the Hamilton depression scale and the Brief Psychiatric Rating Scale (BPRS) (42), the BPRS was also used because it is sensitive to the severity of psychotic symptoms. Scores on the BPRS range from 18 (best) to 126 (worst). Both the Hamilton depression scale and the BPRS were completed by using information from direct observation or from the medical record during the time intervals described. Finally, the Global Assessment Scale (GAS) (43) was used to assess overall level of functioning; scores range from 1 (worst) to 100 (best). This scale is rated using anchor points with brief clinical descriptions at 10-point increments. An estimate of the risk for cerebrovascular disease was made with the ischemic score of Hachinski et al. (44), as

modified by Rosen et al. (45). The interrater reliability of these instruments was reflected by intraclass correlation coefficients of 0.78 or greater.

The physical environment of the inpatient unit was designed to facilitate the care of frail elderly patients, and relatively standardized approaches have been developed for managing dementia and its behavioral complications. Initial attention was focused on the formulation of a comprehensive diagnosis and on minimizing the burden of medical problems that often contribute to functional impairment. Causes of delirium were aggressively sought and appropriate interventions made while supportive care was provided.

Medications were the most common cause of delirium in our clinical setting, although it was often impossible to identify a single cause from among multiple contributing factors. Psychosis (delusions or hallucinations) was treated with high-potency neuroleptics, typically haloperidol, 1–4 mg/day, or perphenazine, 8–24 mg/day. In our experience, higher doses frequently lead to increased confusion from the anticholinergic effects of the medications (25, 46) or to debilitating extrapyramidal side effects, especially parkinsonism (25). Low-potency neuroleptic agents are not well tolerated in equivalent antipsychotic doses because of anticholinergic side effects and symptomatic hypotension.

We have successfully and safely used a variety of antidepressant medications and ECT for the treatment of major depression in patients with Alzheimer's disease. However, our initial treatment of choice for this behavioral complication is nortriptyline, because of the availability of testing of blood levels, which facilitates the adjustment of oral dosages (47), the favorable profile of the drug's side effects (28), and its efficacy in the treatment of major depression in the elderly (28, 29). Therapeutic blood levels (50–150 ng/ml; target=100 ng/ml) (47) are usually reached with doses between 25 and 75 mg/day (28, 29). In the initial stages of the treatment of the patients with Alzheimer's disease and psychosis or depression, antipsychotic or antidepressant medications were often augmented by adjunctive treatment with low doses of short-acting benzodiazepines for symptomatic relief, which were tapered as the behavioral syndromes remitted.

The pharmacologic treatment of behavioral symptoms that occurred in the absence of delirium, psychosis, or major depression was largely empirical and aimed at ameliorating maladaptive behavioral symptoms while producing minimal side effects and without compromising functional ability. Low-dose, high-potency neuroleptic agents, antidepressants, short-acting benzodiazepines, lithium, and carbamazepine were used for this purpose, depending on the behavioral features of the patients and their clinical histories.

In addition to these somatic therapies, patients were provided with supportive individual and group psychotherapy as appropriate. Behavioral techniques were also used, especially for patients whose cognitive impairment limited their ability to benefit from psychotherapy. Finally, education, counseling, and supportive

psychotherapy were provided to family members and caregivers.

Comparisons of continuous sociodemographic and clinical variables among the patients with the different behavioral subtypes of dementia of the Alzheimer type were made using one-way analyses of variance, followed by Tukey post hoc tests when significant group effects were detected. Eighteen of the 120 patients met the diagnostic criteria for more than one behavioral subtype. Comparisons of discrete variables were made with the chi-square test or Fisher's exact test as appropriate. Comparisons of rating scale scores obtained at admission and at discharge were made with the use of paired *t* tests. Associations between continuous variables were explored using the Pearson correlation coefficient. All statistical tests were two-tailed.

RESULTS

As shown in table 1, the group of demented patients studied had a mean age of 79.6 years, and the mean age at onset of cognitive decline was 74.9 years. The group included 75 women (63%), and 10 (8%) of the subjects were black. Eighty (67%) of the patients were living at home prior to admission, while the remainder were living in personal care or nursing homes. The majority of the patients were living on retirement incomes; the mean annual income was \$11,545 (SD=\$6,105). Fifty-nine (49%) of the patients were high school graduates, 16 (13%) had earned a college degree, and three (3%) had earned a postgraduate degree.

The clinical features of these 120 patients are presented in table 1. The Mini-Mental State examination scores for the 98 patients (82%) who were able to participate in this test of cognitive performance ranged from 0 to 27, with a mean of 13.1. The mean modified ischemic score was 2.9, supporting the diagnosis of primary degenerative dementia of the Alzheimer type rather than dementia of vascular origin. The average

number of medical problems per patient was 4.4, and the average length of hospitalization was 27.1 days.

The distribution of *DSM-III-R* behavioral subtypes is also shown in table 1. Only 18 (15%) of the 120 patients met the criteria for more than one category. Since delirium, delusions, and depression occurred alone in 8%, 26%, and 18% of the patients, respectively, 8.5% ($[0.08 \times 0.26] + [0.08 \times 0.18] + [0.26 \times 0.18] + [0.08 \times 0.26 \times 0.18] = 0.085$) would have been expected to exhibit more than one of these subtypes concurrently, a value that did not differ significantly from the observed 15% ($\chi^2=1.92$, $df=1$, $p=0.17$). Twelve of these 18 patients had major depression and delusions, three had delirium and delusions, and three had delirium, delusions, and depression. As shown in table 1, the behavioral subtypes did not differ significantly in age at onset of dementia, age at admission, level of cognitive impairment at admission, or length of hospitalization. Moreover, the proportion of patients able to participate in the Mini-Mental State examination did not differ among the behavioral subtypes ($\chi^2=1.62$, $df=3$, $p=0.65$). In contrast, significant differences in sex, race, ischemic score, and number of medical problems were observed among the behavioral subtypes. Delirium occurred more commonly in men, while delusions and depression were more common in women. In the group with the uncomplicated subtype, the sex ratio was approximately 1:1. Delusions were more common in black patients than in white patients. In fact, nine of the 10 black patients were delusional. Finally, patients with delirium or depression tended to have higher ischemic scores and more medical problems than patients with delusions or the uncomplicated subtype.

We divided the patients into quartiles according to their Mini-Mental State scores at admission, and the frequency distribution of behavioral subtypes across the resulting quartiles is shown in figure 1. The frequency of the subtype with depression decreased with decreasing Mini-Mental State scores, consistent with a previous report (48). None of the other three *DSM-III-R*

^aThe quartile with the highest Mini-Mental State scores contained 23 patients, and each of the remaining quartiles contained 25 patients.

behavioral subtypes showed a consistent relation with Mini-Mental State scores. In contrast, the number of other significant behavioral problems increased with decreasing Mini-Mental State scores ($r=-0.45$, $df=96$, $p<0.001$).

The profile of significant behavioral problems found among the 40 patients with the uncomplicated subtype of Alzheimer's disease is presented in table 2. Patients in this group suffered from a mean of 3.0 (SD=1.7) significant behavioral problems, and only two (5%) had no significant behavioral problems during hospitalization. These two patients were admitted for the diagnostic evaluation of newly identified cognitive decline, suspiciousness, and decreased functional capacity that they evidenced in their residential settings. A comparison of the frequencies of significant behavioral problems in the patients with the uncomplicated and with the other behavioral subtypes is also presented in table 2. Interestingly, with the exception of hallucinations and unspecified problems, the rank order and frequency of each specific behavioral problem were similar in the group with the uncomplicated subtype and the combined group of patients with delirium, delusions, or depression. These findings suggest that the behavioral problems listed in table 2 play an important role in the referral of patients with Alzheimer's disease for inpatient psychiatric treatment and further illustrate the burden of behavioral complications presented by these patients. There was a nonrandom association of hallucinations and delusions ($\chi^2=12.53$, $df=1$, $p<0.001$), supporting the diagnostic validity of psychosis in the context of Alzheimer's disease.

TABLE 2. Significant Behavioral Problems in 120 Patients With the Uncomplicated and Other *DSM-III-R* Behavioral Subtypes of Primary Degenerative Dementia of the Alzheimer Type

Problem ^a	Uncomplicated Subtype (N=40)		Other Behavioral Subtypes ^b (N=80)		Analysis

None	2	5	6	8	0.27	0.61

^aSignificant unspecified behavioral problems included public masturbation or defecation, other significant sexual or social disinhibition, debilitating sleep disturbance, hoarding behavior, and food refusal leading to malnutrition.

^bWith delirium, with delusions, and with depression.

Response to treatment, as reflected by changes in scores on the four psychometric scales, is presented in table 3. The patients with delirium exhibited greater improvement in cognitive performance than the patients with any other behavioral subtype, as reflected by an average change in Mini-Mental State score of more than 4 points. Patients with delirium also exhibited significant improvement in their Hamilton depression scale scores; however, this finding is difficult to interpret in light of the small size of this group and the fact that three of these patients also met criteria for primary degenerative dementia of the Alzheimer type with depression. In spite of their cognitive improvement, patients with delirium did not exhibit significant improvement on the BPRS, and no significant improvement in functioning was observed. Forty-five (92%) of the 49 patients with delusions received neuroleptic medications, and all 37 patients with depression received treatment with an antidepressant, lithium, or ECT. Thirty-two (87%) of the latter group received treatment with nortriptyline. The patients with delusions or depression demonstrated significant improvement on all four scales, with the greatest symptomatic improvement reflected by changes in the BPRS and Hamilton depression scale scores, respectively. The response of the depressed patients was the most vigorous of the four subgroups, as reflected by a 7.0-point average reduction in the Hamilton depression score and a 9.1 average increase in the GAS score, even though this subgroup experienced the greatest number of medical problems (table 1). The patients with the uncomplicated subtype who had mixed behavioral symptoms were the only subtype not to experience consistent, albeit modest, cognitive improvement. However, they did manifest an improvement in the severity of their behavioral problems, as reflected by the Hamilton depression and BPRS scores, and an improvement in overall level of functioning, as reflected by the GAS score.

A comparison of residential setting before admission

with that following discharge is presented in table 4. The proportion of patients who had been living at home was consistent across the behavioral subtypes, ranging from 60.1% to 65.3%. The remaining patients were admitted to the hospital from either personal care or nursing homes. Consistent with the clinical course of Alzheimer's disease and the fact that the typical reason for referral to inpatient care was the inability to manage the patient safely in his or her residential setting, a significant fraction of patients required transfer to a more restrictive setting following discharge. This pattern was consistent across all of the behavioral subtypes except depression, reflecting the greatest symptomatic and functional improvement of this subtype during hospitalization (table 3). In spite of the general trend, 43 (53.8%) of the 80 patients who could no longer be managed at home prior to admission were able to return home following discharge. Moreover, this proportion reached 66.7% (16 of 24) among the subtype with depression. Finally, one patient who had been admitted to a personal care home when he developed restlessness and wandering behavior was able to return home following discharge.

DISCUSSION

Behavioral abnormalities are a common and important source of morbidity and mortality among patients with Alzheimer's disease. However, the diagnosis and treatment of behavioral syndromes and symptoms in

demented patients remain in the formative stages. Our prospective study provided an empirical assessment of diagnostic criteria for the behavioral subtypes of pri-

mary degenerative dementia of the Alzheimer type described in *DSM-III-R*, as well as a quantitative evaluation of response to targeted inpatient treatments based on the resulting diagnoses. Although the patients in our study exhibited a wide range of cognitive impairments, it was possible to reach a consensus on the assignment of each of the 120 patients to one of the four behavioral subtypes by using the criteria described in *DSM-III-R*. The subtypes with delirium, delusions, and depression appeared to occur independently, since only 15% of the patients met the criteria for more than one of these subtypes concurrently. Furthermore, the patients with each behavioral subtype responded to inpatient treatment in a characteristic way, as revealed by changes in scores on the psychometric scales used to assess cognitive impairment, psychiatric symptom severity, and level of functioning. The therapeutic response we observed seemed to be clinically significant as well as statistically significant. While the patients had typically been hospitalized because they could no longer be safely managed at home, half of all patients who had been living at home prior to admission and two-thirds of those with major depression returned home following discharge. In light of the progressive deterioration that is characteristic of Alzheimer's disease, the short-term inpatient psychiatric care provided appears to have been successful.

It should be emphasized that the goal of short-term inpatient treatment was the completion of a thorough diagnostic assessment and the initiation of a comprehensive treatment plan. Discharge occurred when therapeutic doses of medications were achieved and the patient was judged to be sufficiently stable that a safe disposition could be effected with appropriate aftercare. Therefore, our assessments probably underestimated the effects of the treatments initiated, because the maximal benefits of antidepressant and neuroleptic therapy occur 1–2 months after the establishment of optimal doses (28, 49). The interpretation of our quantitative assessments of response to inpatient treatment is also limited by the exclusion of patients who were unable to participate in the assessments at admission or discharge. Unfortunately, this methodologic limitation is inherent in the study of moderately to severely demented patients, especially those who have significant behavioral problems. We addressed this issue by including an analysis of changes in residential setting, which was in general agreement with the psychometric data. It should also be emphasized that our study was naturalistic in its design and was intended to provide an assessment of the aggregate of somatic and other treatment modalities that constitute geriatric inpatient care in our tertiary care setting. The relative contributions of the individual interventions cannot be determined from our data.

Two suggestions for revision of the *DSM-III-R* behavioral subtypes of primary degenerative dementia of the Alzheimer type seem warranted. The use of the uncomplicated subtype to describe psychiatric inpatients with Alzheimer's disease who do not suffer from delirium, delusions, or depression is inaccurate and often

offends family members and other caregivers who have been making their best attempts to manage disruptive and potentially dangerous behavioral abnormalities. Furthermore, the use of this misnomer may jeopardize third-party reimbursement for inpatient treatment in circumstances where it may be clearly indicated. For these reasons, we favor the addition of an additional behavioral subtype for primary degenerative dementia of the Alzheimer type to denote the presence of one or more other significant behavioral abnormalities.

We also favor replacement of the delusional subtype with a psychosis subtype that would include either delusions or hallucinations, since these psychotic symptoms assorted nonrandomly in our inpatient population as well as in a previous longitudinal study of outpatients with Alzheimer's disease (14). As described in *DSM-III-R*, these symptoms constitute direct evidence of psychosis. We do not endorse the use of a broader definition of psychosis because disorganized or aberrant behavior in the context of dementia is often attributable to cognitive impairment rather than a disturbance of reality testing. This definition of psychosis in the context of primary degenerative dementia of the Alzheimer type has also been validated by longitudinal studies that have found the presence of psychosis to be associated with a more rapid rate of cognitive decline (14, 17) and by post-mortem studies that have revealed neuropathological and neurochemical correlates which appear to be relatively specific for psychosis (19). We did not present the data on response to treatment separately for the patients who met criteria for psychosis because this group largely overlapped with the delusional subtype and because the addition of the patients who had hallucinations without delusions did not significantly change the results.

In summary, the diagnosis of behavioral syndromes and symptoms that commonly emerge in primary degenerative dementia of the Alzheimer type is a feasible goal that should not be overlooked, because it has both clinical and prognostic significance. Short-term psychiatric hospitalization provides an effective and efficient means for achieving this goal and for safely implementing treatments that are targeted to specific behavioral complications in this frail population. It may also reduce the need for institutionalization.

Psychiatric Outpatient Practice: Patterns and Policies

Mark Olfson, M.D., and Howard H. Goldman, M.D., Ph.D.

***Objective:** The purpose of this paper is to explore possible consequences of recent changes in the Medicare payment schedule for office-based psychiatric services. **Method:** Psychiatric office visits from the 1985 National Ambulatory Medical Care Survey were categorized in a manner that approximates commonly used codes of the Physicians' Current Procedural Terminology. An analysis was conducted of the frequency and clinical characteristics of various types of services, focusing particularly on visits of under 20 minutes in length that included a medication prescription (medication visits) and other visits of 35 minutes or less in duration (brief visits). **Results:** Medication visits and brief visits together accounted for more than one-quarter (27.3%) of all U.S. psychiatric office visits. The relative risk of receiving these short visits was greater for patients who paid with public resources, were over 65 years of age, were nonwhite in race (brief visits only), received a prescription for an antipsychotic medication, or were diagnosed as having a psychotic disorder. **Conclusions:** Short office visits are provided to a particularly vulnerable patient population. The reduction in Medicare copayments for medication management services should increase the patient demand for these short visits. However, where the new Medicare schedule has lowered physician fees for these services, the financial incentive to provide short visits will decrease and patient access may become limited.*

(Am J Psychiatry 1992; 149:1492-1498)

Psychiatrists in private practice continually grapple with the conflict between a desire to provide comprehensive care and the drive to use time in an efficient manner. The length of time psychiatrists actually spend with individual patients is influenced by a variety of factors. Patient age is inversely related and illness severity is directly related to the amount of face-to-face treatment that patients receive each month (1). Psychiatrists who are influenced by psychoanalytic treatment, practice in medical school settings, or practice in areas that are receptive to mental health services tend to provide comparatively more time-intensive care (1).

Psychiatrists have historically priced brief office visits proportionately higher than standard psychotherapy visits (2). In 1991, the median fee (\$61.00) for a 20- to 30-minute psychotherapy session (code 90843 in the *Physicians' Current Procedural Terminology* [CPT] [3]) was substantially more than half the median fee for a 45- to 50-minute psychotherapy session (\$93.00, CPT code 90844) (4). This pricing strategy has impor-

tant financial consequences. One of the reasons male psychiatrists earn more than female psychiatrists is that male psychiatrists see more patients per hour than their female counterparts (5).

Of the various mental health professions, psychiatry is the most heavily dependent on third-party payment. Although Medicare pays for only a small proportion of outpatient psychiatric care (6), Medicare policies frequently serve as a bellwether for other third-party payers (7). For this reason, mental health policy analysts pay particular attention to the design of Medicare policies.

In December 1987, Medicare expanded its coverage of outpatient psychiatric services provided during "medical management" visits (8). Patient copayment was lowered from 50% to 20% and dollar limits were eliminated. The 50% patient copayment was maintained for all other outpatient psychiatric services. Medicare policy is based on a narrow definition of "medical management," usually brief office visits related to evaluating, prescribing, and monitoring psychoactive medication. This activity typically is given the CPT code for "medication management" (code 90862), although practitioners in some jurisdictions have worked out additional codes. More broadly defined, "medical management" refers to a variety of office visits during which psychotherapy is *not* the dominant activity. Almost any clinical encounter other than a psychotherapy session might be considered in this category. In

Received July 2, 1991; revision received Feb. 19, 1992; accepted March 5, 1992. theory, the "evaluation and management" codes for office visits could be used for medical management. Practice varies from location to location, and there continue to be problems in implementing this concept and the changes in reimbursement it represents.

In January 1992, Medicare began to phase in a new physician fee schedule to control medical expenditures. The new schedule, which is derived from a resource-based relative values scale (RBRVS), arrived at physician fees by analyzing actual practice costs rather than customary or historical charges (9-11). In several areas, the RBRVS schedule substantially reduced physician fees for the less time-consuming outpatient psychiatric services. Psychiatrists in New York City, for example, experienced a 35% reduction in their Medicare fee for 20- to 30-minute medical psychotherapy sessions (CPT code 90843) and a 42% reduction in their fee for medication management visits (CPT code 90862). The reductions for longer outpatient psychiatric services tended to be more modest. For psychiatrists in New York City, there was a 7% reduction in the fee for 45- to 50-minute individual psychotherapy sessions (CPT code 90844) and a 12% reduction for psychiatric diagnostic interviews (CPT code 90801) (12).

The impact of the RBRVS Medicare Fee Schedule varies from location to location. Fees in New York City were adversely affected by the adjustments made for geographic region, which favored rural areas over metropolitan centers. Not every location will experience the same reductions; some will experience an increase in fees, especially for certain categories of visits. In some locations certain services were historically undervalued; in others certain services were overvalued. Although fees for psychiatric outpatient practice will remain about the same in the aggregate, specific adjustments in fees and changing reimbursement policies will alter the incentives shaping supply and demand for ambulatory psychiatric services throughout the nation.

In the current paper, we evaluate how these changes in reimbursement policy may influence office-based psychiatric practice. Data are drawn from the 1985 National Ambulatory Medical Care Survey, and visits are classified to approximate CPT codes commonly used in office practice: psychiatric diagnostic interview (code 90801), medication management (code 90862), individual medical psychotherapy of approximately 20 to 30 minutes (code 90843), and individual medical psychotherapy of approximately 45 to 50 minutes (code 90844). For heuristic reasons, we also analyze visits that are greater than 55 minutes in length.

METHOD

Source of Data

The National Ambulatory Medical Care Survey samples a nationally representative group of visits to physicians in office-based practice. Patient visits are sampled by a one-page data form that was completed by the at-

tending physicians or their office staff. This form contains items such as the patient's age, sex, diagnoses, medications prescribed, and duration of the visit.

The National Ambulatory Medical Care Survey uses a multistage probability sampling design. This involves sampling primary sampling units, sampling physician practices within these units, and sampling patient visits among these physician practices. To reduce duplication of individuals, each sampled physician is randomly assigned to participate during one of the 52 weeks in the survey year. A systematic random sample of visits is selected by the physician during the assigned week. Although this strategy oversamples frequent users of office-based medical care, it accurately reflects clinical activity.

A weighting system was developed by the National Center for Health Statistics to produce national estimates from sample estimates (13). National estimates are obtained by summing the "patient weights." The construction of the patient weights has the following three components: 1) inflation by the reciprocal of the sampling probability, 2) adjustment for nonresponse, and 3) a ratio adjustment to fixed totals. The adjustment for nonresponse replaces patient visits to nonrespondent physicians with visits to respondent physicians in the same specialty and primary sampling unit. The ratio adjustment involves multiplying each visit by the ratio of physicians listed in the master files of the American Medical Association-American Osteopathic Association

Visit Sample

Analyses are presented of visits to physicians who listed their specialty as psychiatry. Psychiatrists include physicians specializing in general psychiatry, child psychiatry, psychoanalysis, and other psychiatric subspecialties. The 1985 National Ambulatory Medical Care Survey surveyed 178 psychiatrists, and the response rate was 74%. A total of 2,703 psychiatric visits were sampled.

Visit Categories

Several of the analyses involve aggregating the psychiatric visits into five mutually exclusive categories. These categories include 1) diagnostic interviews, 2) medication visits, 3) brief visits, 4) standard visits, and 5) extended visits.

Diagnostic interviews include all visits by patients who have not been previously seen by the surveyed psychiatrist and all visits for new psychiatric conditions. Medication visits include all visits of under 20 minutes that include the prescription of a medication. Brief visits include all visits of between 20 and 35 minutes and all visits of less than 20 minutes that do not include a medication prescription. Standard visits include all visits that are greater than 35 minutes and less than 56 minutes in duration. Extended visits include all visits that are greater than 55 minutes.

TABLE 1. Distribution of Office Visits to Psychiatrists Among Solo, Group, and Other Practices^a

Visit Category	Percent		
	Solo Practice	Group Practice	Other

Extended visits	10.0	8.3	9.5 ^c

^aData from 1985 National Ambulatory Medical Care Survey (13) based on 2,703 psychiatric visits. Percents based on weighted sampling.

^bSignificantly different from solo practice ($p < 0.001$).

^cEstimate with relative standard error that exceeds 40%.

^dSignificantly different from solo practice ($p < 0.01$).

^eSignificantly different from solo practice ($p < 0.05$).

^fSignificantly different from group practice ($p < 0.001$).

Diagnostic Groups

The National Ambulatory Medical Care Survey records diagnoses according to ICD-9-CM. In the current report, specific diagnostic codes have been aggregated into seven broad diagnostic groups. These groups include psychotic disorders (codes 290–295, 296.0, 296.1, 296.4–299), depressive disorders (codes 296.2, 296.3, 300.4, 311), neurotic disorders (codes 300.0–300.3, 300.5–300.9), personality disorders (code 301), adjustment disorders (code 309), substance abuse related disorders (codes 291–292, 303–305, 327–328), and a residual category of all other disorders and conditions.

Statistical Methods

The percentages and means provided in the current report are based on weighted estimates. The National Center for Health Statistics provides tables for calculating the approximate standard errors of the survey estimates (13). These tables were used to compute *t* test statistics, and comparisons were made for statistical significance with the two-tailed *t* test and infinite degrees of freedom. Tests of statistical significance are not performed with survey estimates that have an associated relative standard error which exceeds 40%.

Logistic regressions were used to compute the odds ratios of brief visits and medication visits for selected independent variables. The regressions were computed with unweighted data.

RESULTS

General

In 1985, U.S. office-based psychiatrists provided approximately 18 million patient visits. Standard visits accounted for a majority of these contacts (54.3%). Brief visits (20.6%), extended visits (9.7%), diagnostic interviews (8.8%), and medication visits (6.7%) accounted for proportionately fewer visits.

TABLE 2. Geographic Distribution of Office Visits to Psychiatrists^a

Visit Category	Percent			
	Northeast	Midwest	South	West
Diagnostic interviews	6.3	14.4 ^b	8.6	7.3
Medication visits	6.4	8.4 ^c	7.3	4.8
Brief visits	14.9	21.0	29.0 ^d	21.3
Standard visits	65.9 ^e	43.3	44.1	56.5
Extended visits	6.5	13.0 ^d	11.0 ^d	10.1 ^d

^aData from 1985 National Ambulatory Medical Care Survey (13) based on 2,703 psychiatric visits. Percents based on weighted sampling.

^bSignificantly different from Northeast and West ($p < 0.001$) and South ($p < 0.01$).

^cEstimate with relative standard error that exceeds 40%.

^dSignificantly different from Northeast ($p < 0.01$).

^eSignificantly different from Midwest ($p < 0.01$) and South ($p < 0.02$).

Extended visits had the longest mean duration (68.4 minutes), followed by standard visits (47.5 minutes) and diagnostic interviews (47.3 minutes). By definition, medication visits (mean=13.7 minutes) and brief visits (mean=25.5 minutes) were the shortest types of visits.

Type of Practice

Nearly three-quarters (72.5%) of the visits were to psychiatrists in solo practice. The remaining visits were distributed among psychiatrists in group practice (17.6%) and psychiatrists in partnerships or other practice arrangements (9.8%).

Most of the visits provided by psychiatrists in solo practice were standard visits. In contrast, less than a third of the visits provided by psychiatrists in group practice were standard visits. Compared to solo practitioners, psychiatrists in group practice provided a significantly larger proportion of their visits as diagnostic interviews, medication visits, and brief visits (table 1).

Subspecialization

The vast majority of the psychiatric visits were to general psychiatrists (77.8%). A substantially smaller proportion were to psychiatric subspecialists such as psychoanalysts (12.1%), child psychiatrists (8.5%) or other subspecialists (1.6%).

Standard visits accounted for a substantially larger proportion of the visits provided by psychiatric subspecialists (77.8%) than by general psychiatrists (47.8%) ($p < 0.01$). In contrast, medication visits (8.5% versus 0.3%), brief visits (24.8% versus 6.1%), and extended visits (10.5% versus 6.7%, $p < 0.01$) each accounted for a larger percentage of the visits to general psychiatrists than to psychiatric subspecialists. Diagnostic interviews accounted for a nearly even proportion of the visits provided by the two physician groups (general psychiatrists: 8.7%, psychiatric subspecialists: 9.1%).

Geographic Region

Psychiatric visits tended to be concentrated in the Northeast. The estimated rate of psychiatric office visits per 1,000 noninstitutionalized civilians was 127 in the

^bEstimate with relative standard error that exceeds 40%.

^cSignificantly different from medication visits ($p < 0.05$).

^dSignificantly different from diagnostic interviews ($p < 0.05$).

^eSignificantly different from standard visits ($p < 0.001$).

^fSignificantly different from brief visits ($p < 0.01$), medication visits ($p < 0.05$), and diagnostic interviews ($p < 0.05$).

^gSignificantly different from medication visits ($p < 0.001$) and brief visits ($p < 0.05$).

Northeast, 90 in the West, 67 in the Midwest, and 47 in the South.

The distribution of visit categories varied by geographic region. Although standard visits were the most common type of visit provided in each of the four geographic regions, standard visits were particularly common in the Northeast and West. Diagnostic interviews accounted for a significantly larger proportion of the visits in the Midwest than in the other regions. Brief visits were proportionately most common in the South and least common in the Northeast, where extended visits were also comparatively uncommon. Medication visits accounted for less than one-tenth of the visits in each geographic region (table 2).

Patient Demographics

Most of the visits were made by patients who were white (95.2%), female (59.4%), and between the ages of 25 and 44 years (56.2%) and who used either self-payment (57.1%) or commercial insurance (45.1%) to help pay for their visits.

Patients who received medication visits or brief visits tended to be older than patients who received other types of visits. Medication visits and brief visits also tended to be made by a disproportionately high percentage of nonwhite patients and patients who paid for their care with public financing.

Patients who made standard visits were significantly more likely than patients who made diagnostic interviews, brief visits, or medication visits to pay for their care with personal resources. Patients who made stand-

ard visits were also more likely than patients who made medication or brief visits to use commercial insurance (table 3).

Treatment

Psychotherapy, defined as a nonmedication treatment "designed to produce a mental or emotional response through suggestion, persuasion, reeducation, reassurance, or support" (13), was provided during the vast majority (88.7%) of visits. It was provided during approximately half of the medication visits and during more than two-thirds of the other types of visits (table 4).

Medications were prescribed in nearly half (46.3%) of the visits, and most of these prescriptions (85.4%) were for psychotropic medications. As expected, psychotropic medications were prescribed more commonly during medication visits than during any other type of visits. Psychotropic medications were also prescribed in a comparatively high percentage of brief visits (table 4).

The trends observed for the frequency of overall psychotropic medication prescription were also found for specific classes of medications. Antidepressants, anxiolytics, and particularly antipsychotics tended to be more commonly prescribed during medication visits and brief visits than during the other types of visits (table 4).

Diagnosis

The most common primary diagnoses were depressive disorders (29.4%), neurotic disorders (17.6%), psychoses (16.3%), and personality disorders (14.4%).

^aData from 1985 National Ambulatory Medical Care Survey (13) based on 2,703 psychiatric visits. Percents based on weighted sampling.

^bEstimate with relative standard error that exceeds 40%.

^cSignificantly different from standard visits ($p < 0.001$).

^dSignificantly different from diagnostic interviews ($p < 0.05$).

^eSignificantly different from brief visits ($p < 0.001$).

^fSignificantly different from brief visits ($p < 0.01$).

^gSignificantly different from brief visits and standard visits ($p < 0.01$).

^hSignificantly different from brief visits ($p < 0.001$) and standard visits ($p < 0.01$).

Adjustment disorders (9.2%), substance abuse-related disorders (1.7%), and other disorders (11.4%) were less common.

More than one-third of the medication visits and nearly a third of the brief visits were to patients diagnosed with a psychotic disorder. In contrast, fewer than a tenth of the other types of visits were to patients with psychotic disorder diagnoses (table 5).

Personality disorders and neurotic disorders tended to be diagnosed during a larger proportion of standard visits and extended visits than during other types of visits. Adjustment disorders and substance abuse disorders tended to be diagnosed in a larger percentage of diagnostic interviews than in other types of visits (table 5).

Medication Visits

A logistic regression was performed to examine the association between selected demographic, clinical, and practice variables and the occurrence of a medication visit. Visits to general psychiatrists were nearly 20 times more likely than visits to psychiatric subspecialists to be medi-

cation visits. Payment with public funds, patient age over 65, and the prescription of an antipsychotic medication also increased the likelihood of a medication visit. Patients who received psychotic disorder diagnoses were at a slightly higher risk of receiving a medication visit than patients with other diagnoses (table 6).

Brief Visits

The relative risk of receiving a brief visit was increased if the visit was made by a patient who was of nonwhite racial background, was over 65 years of age, or paid with public funds. Physician subspecialization, type of practice, geographic location, patient diagnosis, and neuroleptic medication prescription also significantly influenced the probability of a brief psychiatric visit (table 7).

DISCUSSION

A stereotyped view of private practice psychiatry assumes that psychiatrists devote their time nearly exclu-

TABLE 6. Demographic, Treatment, and Practice Risk Factors for Medication Visits^a

Variable ^b	Odds Ratio ^c	95% Confidence Interval
Age (>65 years versus <65 years)	3.12	1.98–4.94
Sex (male versus female)	1.10	0.79–1.53

^dPublic payment includes Medicare or Medicaid.

sively to the provision of "psychotherapy hours." In fact, the reality is considerably more complex. Psychiatrists provide a broad mix of outpatient clinical services.

In an effort to contain expenditures, third-party payers have developed payment schedules that distinguish various types of office-based psychiatric visits. The most common system for categorizing visits is the CPT (3), and the most influential payment schedule is the Medicare schedule. If recently introduced changes in the Medicare schedule are adopted by other third-party payers, the economics of private practice psychiatry will be significantly altered.

Medication Management

In 1985, medication management visits accounted for an estimated 6.7% of office-based psychiatric visits. Since 1985, Medicare has reduced patient copayments for medication management services and eliminated dollar limits. However, in some locales, the RBRVS has reduced physician fees for these visits. The changes in copayments should increase the demand for medication management visits, but the incentive to provide this service might fall if the fee falls too low. We do not know precisely what to expect, but it would be unfortunate if a policy designed to increase access to services for the "medical management" of mental disorders was foiled by another policy designed to improve fees for "cognitive services" for the same Medicare beneficiaries.

Medication management visits are provided to a particularly vulnerable patient population. Older patients and those who receive antipsychotic medication, suffer from psychotic disorders, or pay for services with public funds are all disproportionately reliant on medication management visits. Fee schedules that do not sufficiently reward physicians for their efforts to treat this patient population may further exacerbate the problem of undertreatment. Epidemiologic evidence suggests that a substantial proportion of persons with the most

TABLE 7. Demographic, Treatment, and Practice Risk Factors for Brief Psychiatric Visits^a

Variable ^b	Odds Ratio ^c	95% Confidence Interval
Age (>65 years versus <65 years)	3.08	2.45–4.85

^dPublic payment includes Medicare or Medicaid.

severe mental disorders do not receive mental health treatment (14).

Brief Visits

In an effort to correct what was deemed as excessive physician fees for shorter office visits, the RBRVS significantly reduced physician fees in several locales for individual medical psychotherapy visits of approximately 20 to 30 minutes in length (CPT code 90844). These brief visits account for approximately one-fifth of visits to office-based psychiatrists.

Certain groups of psychiatrists rely more heavily than others on the provision of brief visits. This group includes general psychiatrists; psychiatrists in group practices, partnerships, or other nonsolo arrangements; and those who practice in the South. These psychiatrists are the most vulnerable financially to fee reductions for brief visits.

The overall public health consequences of reducing patient charges and physician fees for brief visits depend upon how patients and psychiatrists respond. Because utilization of outpatient mental health services is highly price sensitive (15, 16), lowering out-of-pocket expenses may increase patient demand.

How psychiatrists will respond to a cut in reimbursement is less certain. If psychiatrists are willing to see patients during brief visits at reduced fees, brief visits will remain common. If psychiatrists respond by broadening their range of clinical activities and shifting to more lucrative services (17), a shortage may develop in the provision of brief visits. This shortage would have the greatest impact on nonwhite patients, older patients, publicly financed patients, and patients with psychotic disorders.

Other Visits

Depending somewhat on the locale, the new Medicare RBRVS pays physicians for longer outpatient psy-

chiatric services at rates that differ only modestly from historical rates. These visits, which we consider as psychiatric interviews, standard visits, and extended visits, account for a majority of the patient contacts in office-based psychiatric practice.

Patients who receive these longer visits tend to be less severely ill than those who receive shorter visits. Psychotic disorders, for example, are diagnosed in a comparatively small proportion of standard or extended visits. This finding may relate to the consistently negative results of intensive psychotherapy for schizophrenia and other psychotic disorders (18). In other psychiatric conditions, such as depressive disorders (19) and various anxiety disorders (20), the role of more extensive psychotherapeutic interventions is more well established (21, 22).

A small but significant percentage of office-based psychiatric visits exceed 55 minutes in length. The demographic and diagnostic composition of patients who receive extended visits closely resembles that of patients who receive standard visits. Under current CPT coding, psychiatrists have no means of billing for the added effort and expense involved in providing extended visits. If mental health researchers can clearly define the conditions under which extended visits are medically necessary, such as the assessment of acutely dangerous patients, then a rational payment policy can be developed to compensate psychiatrists for their added clinical efforts. Without precise indications for extended visits, it is unlikely that third-party payers will assume the added financial risk of reimbursing these visits at higher than standard rates.

Overview

Rational health care policies seek to promote access to treatment for those in need while controlling overall costs. With the increased differentiation of reimbursement for outpatient psychiatric services, concern has developed that coverage for traditional psychotherapy will be carved out. In fact, the new Medicare RBRVS system may well have the opposite effect. In some areas, sharp reductions in fees for shorter visits threaten to decrease the financial incentives to provide these services, while the relative preservation of fees for longer psychotherapy visits makes these services comparatively more remunerative.

The U.S. mental health care system has been described as two-tiered: one for those with insurance and one for the poor and severely disabled (23). An important criterion for evaluating the success of psychiatric reimbursement policies remains the extent to which they promote equity of access and coverage for those in greatest need.

We have just entered a period of substantial change in the payment for ambulatory psychiatric services. Cost increases and the imposition of a fee schedule could threaten the few gains made in the financing of care for individuals with mental disorders. Future studies should examine the

impact of these changes in policy on trends in the mix of patients served, the content of services, and the pattern of psychiatric outpatient practice.

A National Study of Psychiatrists' Professional Activities

Robert A. Dorwart, M.D., M.P.H., Lee R. Chartock, M.D., Thomas Dial, Ph.D.,
Wayne Fenton, M.D., David Knesper, M.D., Lorrin M. Koran, M.D.,
Philip J. Leaf, Ph.D., Harold Pincus, M.D., Richard Smith, M.D.,
Sidney Weissman, M.D., and Richard Winkelmeyer, M.D.

***Objective and Method:** A mail survey was conducted in 1988–1989 to study the professional activities of U.S. psychiatrists. Data from the 19,431 active respondents are reported. **Results:** Nineteen percent of the psychiatrists were women, an increase from the 17% reported in 1982. The median age of the respondents was 50 years. Nearly one-third of the respondents expressed interest in each of the following areas of subspecialization: adolescent psychiatry, substance abuse, geriatrics, and consultation-liaison psychiatry. More than one-fifth reported formal fellowship training in child/adolescent psychiatry. The psychiatrists worked an average of 48 hours per week—two-thirds in direct patient care—in an average of 2.3 different settings. The proportion of psychiatrists reporting private practice as their primary work setting showed a marked decline from 53% in 1982 to 45% in 1988. There was an increase from 4% in 1982 to 11% in 1988 in those whose primary work setting was a private psychiatric hospital. The typical caseload was over 60 patients, with roughly half that number seen each week. For inpatients treated, the two most common diagnoses were affective disorders and schizophrenic disorders. In a typical week psychiatrists treated about one-half of their outpatients with individual psychotherapy; three-fifths of these were also treated with medications. The average net income for psychiatrists working 35 hours or more per week was \$99,850 for men and \$73,174 for women. **Conclusions:** Major trends evident from this study are subspecialization, medicalization, privatization, feminization, and organizational diversification.*

(Am J Psychiatry 1992; 149:1499–1505)

In psychiatry, as in other medical specialties, the 1990s are a time of transition toward new patterns of activities as the profession adapts to rapidly changing socioeconomic and scientific influences. In the 1980s, advances in treatments, new forms of economic pressures on practice, and a changing mix of characteristics of practitioners, work settings, training, and roles characterized psychiatry (1, 2). To describe better these changes in practice, APA periodically conducts a national census survey of active psychiatrists (defined in detail below) in the United States (3, 4). Reports based

on earlier surveys (5–9) provide a useful background for understanding the present findings. This article reports findings from the ninth, and most recent, study describing psychiatrists' current professional activities, conducted in 1988–1989. The study, supported by APA, was designed and overseen by the Committee on the Biographical Directory and Research on Psychiatric Professional Activities.

This article provides a picture of psychiatrists' professional activities in 1988 and selectively makes comparisons with earlier studies to illustrate trends. For example, the proportion of women practitioners is higher in psychiatry than in most other medical specialties. The proportion of women among active psychiatrists increased by more than 50% between 1965 and 1982, and we found evidence that this trend is continuing (10). Also, because of federal health manpower policies that during the 1970s encouraged medical students to enter psychiatry as a career, we expected to see some evidence of a "resident boom" reflected in the number of middle-aged psychiatrists among currently active practitioners.

Received Oct. 23, 1991; accepted Feb. 20, 1992. From the Office of Research, APA, Washington, D.C., and the Department of Psychiatry, Harvard Medical School, Boston. Address reprint requests to Dr. Dorwart, Malcolm Wiener Center for Social Policy, John F. Kennedy School of Government, 79 Kennedy St., Cambridge, MA 02138.

Major support for this survey was from the APA Committee on the Biographical Directory and Research on Psychiatric Professional Activities. It was supported also in part by NIMH Scientist Development Award MH-00848 to Harvard University (Dr. Dorwart).

This article is not an official APA statement. The views expressed are those of the authors and do not reflect the policies of APA.

METHOD

The Professional Activities Survey was conducted in two phases: APA members were surveyed in 1988 and nonmember psychiatrists in 1989. The member population was defined by the list of all psychiatrists who were APA members in 1988. The total number of members at the time of the survey was 34,164. The number of members responding to the survey was 23,126, or 67.7%. The nonmember population was identified from an American Medical Association list of all U.S. physicians who had identified themselves as specializing primarily in psychiatry. That list was then cross-checked against the APA membership file and duplications eliminated. The result was a residual list of 10,091 self-designated psychiatrists who were not members of APA; questionnaires were mailed to everyone on this list. Some 2,922 completed forms were returned by this group, for an unadjusted response rate of 28.9%. Thus, a total of 26,048 responses were received from member and nonmember respondents. Of the 2,922 nonmember respondents, 341 reported that they were not psychiatrists, and it was determined that 125 were APA members mistakenly included in the nonmember list. In this study, an "active psychiatrist" is defined as one who is neither retired nor a resident/fellow and who is principally engaged in the practice of psychiatry. Combining member and nonmember responses from only the active psychiatrists yielded data on 19,431 active respondents for analysis. For convenience, throughout this article when we use the term "psychiatrists," we are referring to active psychiatrist respondents to our survey.

Some "core" questions appeared on every questionnaire distributed. Others, designated "special topics" questions, were distributed only to subsamples. Each subsample was composed of one-fifth of the total survey population. Some special topics questions were sent to only one subsample and others to two. There were five special topics: treating chronic mental illness, patients' characteristics (diagnoses and demographics), hospital affiliations, economics of practice, and referral patterns.

There are several limitations of this study that should be noted. First, in any survey there is the possibility of response bias. An analysis of demographic characteristics in which respondents were compared with nonrespondents, APA members with nonmembers, and special topics respondents with the entire group of respondents revealed no major differences. Nonetheless, the low response rates of psychiatrists who were not APA members and also for selected items, such as income, are of concern. While they are comparable to response rates for similar independent surveys of physicians' income, these low figures warrant caution. The resulting average incomes, for instance, may be downwardly biased.

Another problem arises when a smaller subsample of respondents answers questions about activities of low frequency, such as the use of specific treatment modalities (e.g., couples therapy or biofeedback). Other limi-

tations of survey methodology inherent in our data involve self-reporting with respect to clinical diagnoses of patients treated, recollection and estimation of weekly or monthly activities, and so forth. In some cases (e.g., specialty board certification), we obtained independent data to validate the accuracy of responses. Although many multipart questions yielded slightly different sample sizes for each item, there remained a large total number of responses to nearly every item.

RESULTS

Demographic Characteristics of Active Psychiatrists

In this survey, 19.1% of the active respondents were women; this compares with 17.3% of the respondents in the 1982 survey of psychiatrists (3, 9). The trend toward an increasing proportion of women in psychiatry is underscored by another study which found that 41% of psychiatric residents in 1987-1988 were women (10). Minorities accounted for 14.6% of the respondents to the present survey, with a slightly higher representation among nonmembers. Asians constituted 8.9%, Hispanics 4.1%, blacks 1.6%, and Native Americans 0.17%. This distribution had changed little from 1982; only the proportion of Asians was up slightly, from 8.3% then. The median age of the psychiatrists in our survey was 49.6 years. This was virtually unchanged from the 1982 APA survey.

Figure 1 presents data on the distribution of active psychiatrists by age category and by gender in 1988. Fewer than 10% of active psychiatrists (excluding residents) were younger than 35 years, and just over 10% were over 65; more than 50% were between 35 and 54. Although the groups are not entirely comparable because of differences in size, a greater proportion of psychiatrists than of general physicians appear to be in the middle age range, with fewer in the younger (below 35) and the older (above 65) categories. Comparing active respondents from the APA surveys of 1988 and 1982 by age group and gender, we found smaller proportions of psychiatrists below the age of 40 and greater proportions between 60 and 69 in the 1988 survey. We also found greater proportions of women in the younger age categories in 1988 than in 1982 (there were few active practitioners younger than 30 in our sample). The "bulge" in the distribution's middle-aged categories (35-50 years) reflects increased numbers of physicians entering the field in the 1960s and 1970s.

Geographic Distribution of Psychiatrists

Over the past 40 years, the numbers of physicians and psychiatrists in the United States have steadily increased, not only in terms of absolute numbers but also in terms of the ratio of physicians to population. For example, in 1970 there were approximately 10 psychiatrists per 100,000 population, and this had increased to roughly 17 per 100,000 by 1988. The dis-

FIGURE 1. Ages of 19,431 Active Psychiatrists Who Responded to a Survey Questionnaire

tribution and rates of growth vary unevenly by region of the country and by state or metropolitan area (3). The psychiatrists we surveyed were disproportionately located in several large urban areas; more than one-fourth of the active respondents were practicing in New York (15.7%) and California (13.0%), while fewer than 1% of all psychiatrists who responded practiced in six rural states. Table 1 illustrates the variation in the ratios of responding active psychiatrists to the populations in regions of the United States, ranging from a low of 3.5 per 100,000 in the southeast to a high of 15.9 in New England.

Specialization in Psychiatry

One of the cardinal features of growth and change in psychiatry in the 1980s was a trend toward subspecialization. We collected several kinds of information that permit us to document this trend: data on training, certification, subspecialty interests of members, types of patients treated, and settings in which psychiatrists work.

Not surprisingly, we found that members' subspecialty organizational affiliations and clinical interests extended beyond formal subspecialty fellowship training, although for child psychiatry there was a rough correspondence in the total number who had formal training (20.9%) and the number who were members of the American Academy of Child and Adolescent Psychiatry (20.5%). Of respondents who expressed *interest* in a subspecialty, more than 30% indicated adolescent psychiatry, alcohol abuse, consultation-liaison, or geriatric psychiatry as the area of interest; more than 20% indicated administrative psychiatry, child psychiatry, or forensic psychiatry. An interest in research was expressed by 12.8%, while 3.0% reported having at least 1 year of formal training in research. Two other established formal subspecialty areas (in which respondents had fellowships of at least 1 year) were administrative and community psychiatry (1.4%) and consultation-liaison psychiatry (1.5%). Newer specialties had small but growing representation among formal subspecialty fellowship trainees: forensic, 0.7%; geriatric, 0.7%; and substance abuse, 0.4%.

TABLE 1. Active Psychiatrists in Regions of the United States in 1988 According to 19,183 Survey Respondents

Region ^a	Number of Psychiatrists	Population (in thousands) ^b	Ratio ^c
Southwest central	1,278	26,885	4.8
Northeast central	2,438	42,119	5.8
Northwest central	943	17,759	5.3
Pacific	3,395	37,351	9.1
Southeast central	544	15,344	3.5
South Atlantic	2,937	41,809	7.0
Mountain	836	13,328	6.3
Middle Atlantic	4,753	37,631	12.6
New England	2,059	12,963	15.9

^aThis regional analysis excludes the District of Columbia.

^bRegional population estimates for 1988 were taken from the *Statistical Abstract of the United States, 1990*.

^cRatios are based on the number of active, responding psychiatrists per 100,000 resident population.

Many psychiatrists pursue their subspecialty interests through participation in specialty societies or organizations, including training that is not necessarily full-time fellowship education. To illustrate, 7.2% were members of the American Academy of Psychiatry and the Law, 4.2% belonged to the American Academy of Psychiatrists in Alcoholism and Addictions, and 5.2% were members of the American Association for Geriatric Psychiatry. Approximately 8% also belonged to the American Society for Adolescent Psychiatry and 20.7% to the American Psychoanalytic Association and the American Academy of Psychoanalysis combined. Cross-membership in organizations such as the American College of Neuropsychopharmacology (1.7%) or the Society of Biological Psychiatry (3.5%) is consistent with the research interests of many psychiatrists. Affiliation with the following other scholarly or professional organizations reflects not specialty orientation per se but, rather, broad identification with medicine or other aspects of the profession: American Medical Association (56.4%), American College of Psychiatrists (6.1%), American Orthopsychiatric Association (7.6%), and Group for the Advancement of Psychiatry (4.0%).

Practice Activities of Psychiatrists: Settings and Time

Psychiatrists worked in a wide variety of settings, and most worked in more than one setting. The mean number of settings was 2.3 in 1988, as it was in 1982. For example, a psychiatrist might work half the time in a medical school, involved in teaching and research, and one-quarter of the time in a local community mental health center (CMHC) and also maintain a part-time private office practice and be a consultant to a nursing home. In general, psychiatrists' practices have been characterized over the past 25 years by a predominance of private practice over other primary work settings and by a large and growing involvement in organization-based practice (11, 12, 13 [p. 81]).

In 1988 the proportion of psychiatrists reporting private practice, alone or in an office-based group, as their primary activity (i.e., the setting where they worked the

FIGURE 2. Primary Work Settings of 19,431 Active Psychiatrists Who Responded to a Survey Questionnaire

greatest number of hours in a typical week) was 45.1%, compared to 57.7% in 1982 (figure 2). On the other hand, private office practice remained the second most common secondary work setting, with 25.8% of the respondents reporting this in 1988. In contrast to the reduction in private practice, the proportion of psychiatrists who worked in private, free-standing, specialty psychiatric hospitals rose from 3.7% in 1982 to 11.4% in 1988. The proportion in *solo* private practice was 38.2% in 1988. Nearly 16% of all respondents indicated a state hospital as their primary work setting. Of the active respondents, 26.5% worked exclusively in one setting, while 37.9% worked in three or more settings per week. One of the most common patterns among psychiatrists was to combine organizational work with a part-time private practice. Those who worked in private and other (primarily general) hospitals were the most likely to have a part-time private practice.

Figure 3 shows how psychiatrists allocated their time. The average paid work week for psychiatrists was 48 hours, unchanged since earlier studies in 1982 and 1970. Direct patient care occupied more than two-thirds (67%) of all work time for psychiatrists. Time devoted to other professional activities, such as administration, teaching, consultation, and research, is also shown in figure 3. An *additional* 8 hours per week of professional activity was unpaid.

Trends in Patient Characteristics and Treatment Modalities

Respondents reported a mean of 32.6 hours of direct patient care per week; the median was 34 hours. Again, this represents two-thirds of all professional effort (figure 3). These figures vary across work settings, thus affecting the average number of patients seen in different work settings. Considering only patients treated in the respondents' primary work setting, we found that psychiatrists whose primary work setting was a CMHC treated the largest number of patients per week, an average of 35 patients. Psychiatrists whose primary work

FIGURE 3. Percentages of Time Spent in Professional Activities by 19,431 Active Psychiatrists Who Responded to a Survey Questionnaire

setting was a private office practice or a health maintenance organization (HMO) treated an average of 30 patients per week, compared to 20 per week treated by psychiatrists working primarily with inpatients in private psychiatric hospitals. The significance of this difference for the quality of care rendered is unknown; some of the divergence is probably caused by differences in the proportion of patients requiring individual psychotherapy and to differences in psychiatrists' non-clinical responsibilities in public versus private settings. Psychiatrists whose primary work setting was a medical school or a government agency treated the smallest numbers of patients per week, approximately 11 and six patients, respectively. This is most likely because of their other professional responsibilities, such as teaching, administration, and research. The number of patients seen per week in 1988 in most settings was quite similar to the number reported in the 1982 APA survey (13).

Treatment Settings

Treatment settings can be grouped into outpatient, inpatient, and partial hospitalization categories. The figures represent the average caseloads of all psychiatrists who reported treating *any* patients in a given kind of treatment setting, not the caseloads of psychiatrists whose primary workplace was one of these settings. Psychiatrists treated a mean monthly caseload (different patients seen at least once) of 47 patients (median=35) in outpatient settings. They saw a mean monthly caseload of 31 different patients (median=22) in inpatient settings and a mean of 21 different patients (median=11) in partial hospitalization settings. Because the intensity of service is typically greater in inpatient and partial hospitalization settings, psychiatrists carry smaller monthly caseloads in these settings.

When patients seen at least once during the preceding month were grouped according to their principal diagnosis, the five most common diagnostic categories

among outpatients were affective disorders (26.3%), anxiety disorders (14.3%), schizophrenic disorders (12.6%), personality disorders (11.0%), and adjustment disorders (7.9%). The five most common diagnoses among inpatients were affective disorders (21.2%), schizophrenic disorders (17.9%), alcohol-related disorders (9.4%), personality disorders (8.4%), and organic mental disorders (8.2%). In partial hospitalization settings, the five most common diagnostic groups were schizophrenic disorders (30.2%), affective disorders (15.9%), disorders of childhood (11.1%), developmental disorders (9.1%), and personality disorders (7.1%). Figure 4 shows the distribution of diagnoses in the three kinds of settings combined. The validity and reliability of these diagnoses is unknown, since they are based on psychiatrists' self-reports. However, patients with schizophrenia, who represent only 5% of individuals with diagnosable mental disorders (14), represented a much larger proportion of the responding psychiatrists' caseloads.

In outpatient settings, during a typical work week psychiatrists treated about one-half (52.1%) of their patients with individual psychotherapy; of these patients, three-fifths (60.5%) were also treated with medications. About one in six patients (17.9%) received medication management alone. More than half (54.5%) of the psychiatrists' patients received pharmacological treatment, alone or combined with psychotherapy. About one in seven outpatients (14.6%) was seen for assessment and evaluation, which may or may not have led to further treatment. Psychiatrists' medical training is essential for both pharmacotherapy and the evaluation of new patients, which together involved more than two-thirds of their outpatients. Contrary to popular perception, only 2.7% of psychiatrists' outpatients were engaged in psychoanalysis. About one in 25 outpatients (4.3%) participated in group psychotherapy and a similar proportion (4.2%) in couples therapy.

ECT was rarely administered on an outpatient basis (0.5% of patients), which is consistent with the APA task force recommendation that this treatment be reserved for "a carefully selected population of patients" (15, p. 34). Fewer than one in 10 psychiatrists (7.4%) nationwide had utilized ECT in the month before responding to the 1988 survey (roughly 6% of the total sample had used ECT for five or fewer patients, and about 1% had used ECT with a greater number of patients). Less than one-tenth of one percent of outpatients were treated with ECT.

Psychiatrists' Incomes

Psychiatrists' incomes are often reported to be lower than those of most other medical specialties; however, these reports mask wide variations (16). We asked respondents to report salaried and nonsalaried income and professional expenses. We calculated the mean annual income of psychiatrists practicing more than 35 hours per week. For men the mean net income in 1988 was \$99,850 (in 1988 dollars), and for women the

FIGURE 4. Distribution of Caseloads, by Diagnostic Category, of 19,431 Active Psychiatrists Who Responded to a Survey Questionnaire

mean was \$73,174. Besides the marked differences by gender, there were also wide differences by region of the country and by primary work setting. To illustrate, for male psychiatrists working 35 hours or more, the mean net income in the southwest central region was roughly \$105,000 annually, compared to approximately \$85,000 in the northeast. According to primary work setting, private practitioners reflected the mean (\$99,864), while those in private psychiatric hospitals earned \$116,000, and those in state or federal hospitals reported a lower mean income (\$84,000).

DISCUSSION

Psychiatry shares with other medical subspecialties a predominant reliance on private practice as the major setting and form of activity. However, the growth of other settings for practice, such as hospitals, HMOs, preferred provider organizations (PPOs), and group practices, could be expected to reduce reliance on office-based private practice. We therefore expected to see evidence of changes in primary work settings and to see increasing subspecialization in clinicians' training, interests, types of patients treated, and modalities of therapy used. We were also interested in influences related to major changes in the financing and organization of care, such as the impact of growing competition on psychiatric practice and on incomes of psychiatrists (11). Our results represent more than isolated changes, for we see several major trends influencing professional practice that are likely to continue in the 1990s. For example, a combination of sociodemographic, scientific, economic, organizational, and professional forces have converged to bring about the current growth of psychiatric subspecialization in geriatrics, addictions, and other fields. We review and discuss here some of the trends and implications of the major findings of our survey.

1. Feminization. As psychiatry grows, new demo-

graphic patterns are emerging. Most strikingly, more women are entering psychiatry than ever before, a trend some observers have called "feminization." Actually, more women are entering medicine generally, and several specialties (e.g., pediatrics, obstetrics/gynecology) are experiencing increases in the proportions of young women in those fields. Because of an increase in the average age of practitioners in psychiatry, this increased attraction of women into the profession seems fortunate. This trend toward older practitioners undoubtedly reflects a gradual decline in interest in careers in psychiatry following a peak in the 1960s and 1970s. These trends deserve further attention from researchers in the future.

Future research should explore these findings in more depth. For example, because of recent entry into active practice, women in psychiatry are disproportionately in the younger age categories. Is that why women report significantly lower average annual net salaries than do men? Or is it because, on average, women in the middle-aged categories work 10% fewer paid hours per week than do their male counterparts? In our survey, women were overrepresented in the younger age category, were slightly overrepresented among those who were salaried, and worked more frequently in the public sector (e.g., women were represented 2:1 in CMHCs). In terms of types of patients seen, female psychiatrists see more children and adolescents and fewer patients with substance abuse disorders. It is also possible that with all employment characteristics held constant, women are paid less because of gender and/or age bias. A thorough analysis of these sorts of differences is beyond the scope of this article. The issue, however, deserves further attention.

2. Organizational diversification. We found a decline in the proportion of psychiatrists who consider private office-based practice their primary work setting. At the same time, there has been an increase in the proportion whose primary work setting is in an organization. These findings result from several concurrent trends influencing health care generally. During the 1980s there was a dramatic growth in HMOs, PPOs, and group practices, which undoubtedly underlies some of the decline in solo private office practice (17). There was also a dramatic increase during the 1980s both in the number of private psychiatric hospitals and in the number of psychiatric units in general hospitals (18). Thus, underlying the trend toward greater involvement of psychiatrists in hospitals seem to be the larger trends of privatization and medicalization.

Significantly, psychiatrists continue to treat patients who have severe mental illnesses, such as schizophrenia and major depression. Altogether, our data reveal that a majority of patients seen by psychiatrists have some sort of "medical" involvement, such as taking psychiatric medications, requiring biomedical diagnostic tests, receiving other somatic therapies, or, in the case of patients with co-occurring medical conditions, receiving consultation. Psychiatric work in hospital settings, including private facilities, is increasing. There

is, simultaneously, an increase in psychiatrists' involvement (numerically and proportionately) in public settings, such as state, county, and municipal mental hospitals, Department of Veterans Affairs hospitals, and CMHCs. In all, public settings as the primary work site were reported by 25.0% of the psychiatrists, while 33.1% reported some type of hospital as their primary work setting.

3. Subspecialization. Our findings document the widespread impression of growing subspecialization in psychiatry. Our respondents frequently indicated multiple subspecialty interests, formal fellowship training, extensive membership in subspecialty organizations, and a considerable number of patients seen weekly in particular categories involving special skills, such as treatment of children, substance-abusing inpatients, or the elderly. For example, in terms of expressed subspecialty interests (primary, secondary, or tertiary), about 20% of the respondents mentioned child psychiatry and about 30% geriatric psychiatry. Psychoanalysis, substance abuse, and forensic psychiatry also had significant representation. Subspecialization has long been evident in the scientific and clinical pursuits of psychiatrists; however, recently there has been an accelerating trend toward formalization of subspecialties (19). In April 1991 the American Board of Psychiatry and Neurology gave its first examination to confer a certificate of added qualifications in geriatric psychiatry. Several other subspecialties (e.g., addictions, forensic psychiatry, administrative psychiatry, adolescent psychiatry, and consultation-liaison psychiatry) have requested similar status.

Additionally, in terms of professional roles, administration and research may be viewed as important subspecialties within psychiatry. Eleven percent of all professional time of psychiatrists is reportedly devoted to administration; 1.4% of the respondents reported fellowship training in administration, and APA has a separate certifying board for this activity. Administration is an important primary function of many psychiatrists, especially in public mental health agencies. As for research, 80% of the psychiatrists reported no such activity; however, about 20% spent at least 1 hour weekly. More meaningfully, 1.6% devoted 20 hours or more per week to research. Finding ways to increase entry into, training in, and long-term support for substantial research careers should be a high priority for advancement of the field.

CONCLUSIONS

The 1990s, the "decade of the brain" (20), portend rapid changes in the science and practice of psychiatry. The many changes in professional activities that are familiar to practicing psychiatrists are also documented in the patterns and trends found in this study. New treatments imply new forms of training and new ways to meet clinical needs of patients. Rapid changes in the financing and organization of care require individuals

as well as organizations to adapt to new health care delivery systems. In sum, we see evidence of more specialization and medicalization of clinical practice, more diversification of practice settings, and increased involvement in systems of organized care; private practice continues to decline as a primary work setting. More women are entering the field, and this trend will undoubtedly influence the profession in ways yet to be seen. It is therefore important that researchers of psychiatric services be prepared to monitor and analyze the magnitude and direction of future changes in psychiatric practice.

Regional Cerebral Glucose Metabolism in Bulimia Nervosa

Paul J. Andreason, M.D., M.S., Margaret Altemus, M.D., Alan J. Zametkin, M.D.,
Anna C. King, Julio Lucinio, M.D., and Robert M. Cohen, M.D., Ph.D.

***Objective:** The authors' purpose in this study was to further delineate the character of cerebral metabolism in bulimia nervosa and to determine if functional links could be made between regional cerebral metabolism and the symptoms of depression, obsessive-compulsive disorder, and bulimia nervosa. **Method:** Regional cerebral glucose metabolism was measured by using positron emission tomography in 11 inpatients with bulimia nervosa and 18 normal comparison subjects matched in sex (all were women), age, and educational level. The bulimic patients were also tested for symptoms of major depression and obsessive-compulsive disorder. **Results:** The patients with bulimia showed a correlation between lower left anterolateral prefrontal regional cerebral glucose metabolism and greater depressive symptoms. However, the orbitofrontal regional cerebral glucose metabolism of patients with bulimia was not greater than that of comparison subjects, nor was higher orbitofrontal metabolism correlated with greater obsessive-compulsive disorder symptoms. **Conclusions:** These findings lead to the conclusion that left anterior lateral prefrontal cortex hypometabolism varies with the depressive symptoms observed in bulimia but that temporal lobe hypermetabolism and asymmetries appear to be independent of the mood state.*

(Am J Psychiatry 1992; 149:1506-1513)

Positron emission tomography (PET) with [^{18}F]-fluorodeoxyglucose (FDG) offers a method for examining the functional metabolic activity of brain regions. Our purpose in this study was to further delineate the character of cerebral metabolism in bulimia nervosa and to determine if functional links could be made between regional cerebral metabolism and the symptoms of depression, obsessive-compulsive disorder, and bulimia nervosa.

Bulimia nervosa is a psychiatric disorder characterized by rapid, uncontrolled, and compulsive ingestion of large quantities of food during discrete periods of time (binge eating), the regular use of extreme efforts to control weight (e.g., vomiting, laxative or diuretic abuse, vigorous exercise), and a persistent overconcern with body shape and weight (*DSM-III-R*). It is most commonly seen in young women.

The etiology of bulimia nervosa is unknown but may involve neurochemical, neuroendocrine, genetic, and psychosocial factors (1-3). Symptoms of major depression and obsessive-compulsive disorder often accompany bulimia nervosa. Because of this, clinicians have approached bulimia nervosa through treatment plans

that model the disorder as a mood disorder, as a personality disorder, as obsessive-compulsive disorder, or as a unique pathophysiological entity.

Wu et al. (4) and Hagman et al. (5) studied one set of PET data from a group of eight women with bulimia nervosa. These authors reported different patterns of hemispheric metabolism among three groups—normal volunteers, depressed patients, and patients with bulimia nervosa. Although patients with bulimia nervosa have a very high rate of depression and depressive symptoms (3), these authors did not find a metabolic correlation between bulimia nervosa and depression.

Bulimia nervosa is associated with major depression and obsessive-compulsive disorder, and both have been studied with FDG PET (6-10). Baxter et al. (6) found that lower regional cerebral metabolism of the left anterior lateral prefrontal cortex correlated significantly with greater severity of depressive symptoms. Lower metabolism of the right anterior lateral prefrontal cortex also correlated with greater depressive symptoms but less strongly.

Reduced activity of the left anterior lateral prefrontal cortex has also been implicated in depression secondary to stroke. Robinson and Starkstein (11) found that damage to the left anterior lateral prefrontal cortex correlated significantly with a higher incidence of major depressive episode. Damaged areas that were further from the left anterior lateral prefrontal cortex were less associated with depression than those closer to the left anterior frontal pole.

Baxter et al. (6) studied patients with obsessive-com-

Presented at a New Research session at the 144th annual meeting of the American Psychiatric Association, New Orleans, May 11-16, 1991. Received Aug. 19, 1991; revision received March 11, 1992; accepted March 27, 1992. From the Section on Clinical Brain Imaging, Laboratory of Cerebral Metabolism, and the Clinical Neuroendocrinology Branch, NIMH, and the Section on Electrophysiology and Brain Imaging, Laboratory of Clinical Studies, National Institute on Alcoholism and Alcohol Abuse. pulsive disorder who did or did not have concomitant major depression and found that left anterior lateral prefrontal cortex regional cerebral glucose metabolism varied with depressive symptoms but orbitofrontal hypermetabolism was present in patients in the absence of clinical depression. Nordahl et al. (7) and Baxter et al. (8) found that patients with obsessive-compulsive disorder had higher orbitofrontal metabolic rates.

Patients with bulimia nervosa experience perturbations of appetite and eating behavior, and these symptoms and signs often persist in the absence of depressed mood. Thus, certain regional cerebral glucose metabolism abnormalities in bulimia nervosa might be expected to be associated with depression but others might be independent of mood state and obsessiveness. One could then infer that these areas might be associated with the core eating behaviors of bulimia nervosa.

Patients with bulimia nervosa experience obsessive thoughts (regarding food and body weight and image) and have compulsive eating behaviors. It would therefore be interesting to see if there were a link between the clinical obsessive-compulsive disorder symptoms of bulimia nervosa and orbitofrontal metabolism. Such an examination was not reported by Wu et al. (4) or Hagman et al. (5).

METHOD

Subject Selection

Our 11 bulimic subjects were inpatients at the National Institutes of Health on a unit for eating disorders. Patients admitted to this study were initially screened to establish the diagnosis of bulimia nervosa by *DSM-III-R* criteria and to exclude medical illness, neurological illness, and histories of psychotic episodes, seizures, CNS infection, or loss of consciousness. All subjects chosen were women who were between 85% and 115% of their appropriate average body weight according to actuarial tables. All patients binged and vomited at least once a day. All patients gave written consent after information about radiation doses and procedures were explained fully.

The bulimic patients were evaluated for symptoms of obsessive-compulsive disorder and major depression with the Maudsley Obsessive-Compulsive Inventory (12) and the Hamilton Rating Scale for Depression.

For the first week, patients were allowed to live on the ward without the staff interfering with their eating behavior except for round-the-clock monitoring. Routine blood chemistries, ECGs, and physical examinations were conducted to assure that all patients were in no imminent physical danger if they continued this behavior. Patients consented to and were aware of being observed. Binge eating and purging frequency were documented in this fashion.

After the first week, patients entered a phase during which they were abstinent from binge eating and purging. During this phase patients received group and individual supportive psychotherapy and behavior modification but no psychotropic medications. This is the phase during

which PET scanning was performed. Each patient's caloric intake was closely monitored on a closed ward setting. The patients had been abstaining from binge eating and purging behaviors for at least 3 weeks but no more than 5 weeks when the PET scans were obtained. They maintained a constant (± 1 kg) normal body weight (85%–115% of the appropriate average).

Finally, the patients entered an open clinical phase during which they could make choices about receiving appropriate psychotropic medication and/or continuing psychotherapy. The average inpatient stay was 9 weeks.

The 18 nonpatient comparison subjects, who were normal volunteers, were matched with patients for age, sex, and educational level. Their mean age was 25.3 years ($SD=3.7$), compared with 25.5 ($SD=3.5$) for the patients, and their mean number of years of education was 15.6 ($SD=2.7$), compared with 14.2 ($SD=1.8$) for the patients. Comparison subjects were screened for a history of psychiatric, neurological, and medical illness. Results of physical examination and laboratory tests, including thyroid function tests, were within normal limits.

Scanning Procedure

All subjects were scanned 2–3 hours after a light meal. After information was provided and consent was given, intravenous and arterial lines were placed for tracer administration and serial blood sampling. If radial arterial line placement was unsuccessful, blood sampling was done from a second intravenous site that was "arterialized" with a local heating pad. Subjects were placed on the scanner table, and their heads were immobilized with a thermoplastic mask.

After aligning the PET camera to the canthomeatal line, a 7.5-minute transmission scan was performed for measured attenuation correction.

Subjects' eyes were covered and headphones were used while 5 mCi of FDG was administered and subjects performed a continuous discrimination task for 30 minutes (13). At the end of this 30-minute period, the headphones were removed and four scans of seven slices each were acquired over the next 30 minutes. During this time, serial blood samples were obtained so that a time-activity curve could be constructed and to verify that blood glucose was stable. The conversion of image pixel values from nanocuries per cubic centimeter micromoles of glucose per minute per 100 g tissue was performed by using methods described elsewhere (14–17).

Scanning was done on the Scanditronix PC1024-7B PET scanner. This scanner's in-plane resolution is 5.2 mm (resolution full width half maximum) at the center of the gantry. The axial resolution (slice thickness) is 10 mm at the center of the gantry, and the slice separation is 3.5 mm.

Data Analysis

The data were analyzed from both a hypothesis-driven approach and a systematic approach. Since previous studies have found correlations between depres-

FIGURE 1. Lateral View of Placement of Regions of Interest for PET Study

sive symptoms and activity in the left anterior lateral prefrontal cortex, differences in the orbitofrontal cortex between bulimic patients with obsessive-compulsive symptoms and comparison subjects, and differences in asymmetries in the temporal lobes between bulimic patients and comparison subjects, we used a univariate approach specifically to analyze differences in these regions. For the sake of completeness, the remainder of the cerebral regions are reported without correction for multiple comparisons.

To analyze the data in both a hypothesis-driven and a systematic manner, a template of 60 regions of interest was placed on PET slices by two independent raters who were not aware of the subjects' diagnoses. Slice selection and region placement, described elsewhere (13), were visually selected by the rater to match structures illustrated in the Matsui-Hirano atlas of the human brain (18). Figure 1 presents a lateral view of the placement of regions of interest.

Global cortical gray matter metabolic rates were calculated by finding the mean of the 49 cortical regions. Normalized regional cerebral glucose metabolic rates were calculated by dividing the regional cerebral metabolic rates by the global cortical gray matter metabolic rate (19).

Normalized regional cerebral glucose metabolism values of diagnostic groups were compared by using unpaired *t* tests and analysis of variance where appropriate. Nonmidline homologous hemispheric pairs of regions were compared by using paired *t* tests to evaluate for asymmetry. Scores from clinical rating scales, cognitive tests, and observed rates of binge eating and purging were correlated with regional cerebral glucose metabolism values by using linear regression. Two-tailed *t* tests were used unless otherwise indicated.

RESULTS

The patients with bulimia and the comparison subjects did not differ with respect to their global gray glu-

cose metabolic rates (49.8 μ moles glucose/minute/100 g tissue, SD=8.8, versus 54.5 μ moles glucose/minute/100 g tissue, SD=9.4). Bulimic patients had significantly lower absolute glucose metabolism in the right anterior frontal region of plane B (49.01 μ mol/min/100 g tissue, SD=9.78) than comparison subjects (58.26 μ mol/min/100 g tissue, SD=11.18) (*t*=-2.27, *df*=27, *p*=0.03).

Figure 2 and tables 1 and 2 present normalized regional glucose metabolism values in the prefrontal and temporal cortex of the patients with bulimia and the comparison subjects. The patients with bulimia had sig-

^aValues are micromoles of glucose per minute per 100 g of tissue.

164.1 correct identifications (SD=55.4), and the comparison subjects had a mean of 187.7 (SD=29.5). The patients had a mean of 4.1 false alarms (SD=4.2), and the comparison subjects had a mean of 10.1 (SD=14.1).

Nonmidline regions were analyzed for asymmetry to compare our results from this group of subjects with those of Wu et al. (4). Table 3 summarizes these results. Asymmetry of glucose metabolism was found in the comparison group in plane C in the anterior prefrontal regions and in plane D in the parietal temporal regions and the caudate (table 3). The prefrontal and caudate asymmetries found in the comparison subjects were not found in the bulimic patients, but the plane D parietal temporal asymmetry was present (table 3). Additional asymmetries were found in bulimic patients in plane B in the anterior frontal regions, in plane A in the posterior frontal regions, and in plane D in the middle temporal region and the posterior putamen (table 3).

There were only three hemispheric pairs that statistically differed between groups. Patients with bulimia had greater left-sided than right-sided activity than comparison subjects in plane B in the anterior frontal regions ($t=3.21$, $df=27$, $p=0.003$) and parietal regions ($t=2.30$, $df=27$, $p=0.03$). Patients with bulimia also had greater right-sided than left-sided activity than comparison subjects in plane D in the caudate ($t=-2.12$, $df=27$, $p=0.04$).

The regional cerebral glucose metabolism in the plane E orbitofrontal regions of bulimic patients was compared with that of comparison subjects and correlated with the patients' scores on the Maudsley Obsessive-Compulsive Inventory. The patients with bulimia nervosa did not have higher orbitofrontal metabolism than the comparison subjects, nor did their metabolism in these regions correlate positively with their scores on the Maudsley Obsessive-Compulsive Inventory. Two of the orbitofrontal regions in bulimic patients correlated negatively with higher Maudsley scores (anterior medial, $F=8.12$, $r^2=0.47$, $df=10$, $p=0.02$; left anterior, $F=9.23$, $r^2=0.51$, $df=10$, $p=0.01$). There were nonsignificant trends toward negative correlations with higher Maudsley scores in the other three orbitofrontal regions.

Correlations between prefrontal and temporal areas and Hamilton depression scale scores in the bulimic patients were tested by using simple regression. In plane C, the left anterior ($F=4.99$, $r^2=0.38$, $df=9$, $p=0.03$, one-tailed t test) and the left posterior ($F=5.92$, $r^2=0.42$, $df=9$, $p=0.02$, one-tailed t test) prefrontal regional glucose metabolism correlated negatively with higher Hamilton depression scale scores. There was a trend toward negative correlation with higher Hamilton depression scale scores in plane C in the right anterior prefrontal region ($F=3.02$, $r^2=0.27$, $df=9$, $p=0.06$,

one-tailed *t* test) (figure 3), but other prefrontal and temporal regions were not significantly correlated with the Hamilton depression scale scores. When the patients whose Hamilton depression scale scores were 15 or greater (18 comparison subjects and seven patients with bulimia) were considered separately, mean regional cerebral glucose metabolism values in the left anterior and posterior lateral prefrontal cortex were significantly lower than those of comparison subjects ($t=-1.96$, $df=23$, $p=0.03$, and $t=-1.83$, $df=23$, $p=0.04$, respectively, one-tailed *t* test).

At the time of the PET scan, these bulimic patients had abstained from binge eating and purging for at least 3 weeks but not more than 5 weeks. Neither the frequency of their pre-abstinence binge eating nor their caloric intake correlated with prefrontal or temporal metabolism. The frequency of binge eating episodes did correlate positively with higher metabolism bilaterally in the posterior frontal area of plane A and in the right parietal area of plane A. These areas were not considered in any a priori hypothesis and were not significant after correction for multiple comparisons.

CONCLUSIONS AND DISCUSSION

This study presents a controlled and systematic view of a complex clinical syndrome. Great care was taken to assure that regional differences and correlations were not influenced by metabolic factors due to electrolyte imbalance, starvation states, or lack of homogeneity due to binge eating and purging. At this point we would like to comment on two issues with regard to data analysis: statistical interpretation of multiple comparisons and localization of anatomical structures on the PET image.

With regard to the analysis of multiple regions, a template of 60 regions was used to standardize the blind rating process and our approach to the examination of PET images. Regions selected for statistical comparisons in this work were divided into two groups: 1) regions based on a priori hypotheses formed from metabolic asymmetry, clinical correlations, and mean regional metabolic differences found in other work (4–8, 11) and 2) other regions reported for the benefit of the reader. We did not correct for multiple comparisons in the analysis of regions for which we had a priori hypotheses because this would be statistically unwarranted and overly magnify the possibility of making type II errors. Other regions were analyzed on an exploratory basis and probability values were reported without corrections for multiple comparisons so that the reader might judge their possible significance or lack thereof. This type of statistical treatment is consistent with several articles (6, 7, 10, 13).

Localization of anatomic structures was accomplished by using the Matsui-Hirano atlas of the human brain (18). This method has proven reliable as used by our group. Using this method we have been able to replicate the findings of hypermetabolism in the orbitofrontal lobes in pa-

FIGURE 3. PET Images of C-Plane Slice of Left Anterolateral Prefrontal Cortex of Three Bulimic Inpatients With Different Hamilton Depression Scale Scores^a

^aThe numbers indicate the patients' Hamilton depression scale scores.

tients with obsessive-compulsive disorder and hypometabolism in the left anterolateral prefrontal cortex in depression reported by Baxter et al. (6, 8) and Nordahl et al. (7). There are other methods of anatomic localization that use computer fitting of magnetic resonance imaging (MRI) or computed tomography (CT) scans. These systems were not available to us at the time this data set was acquired, and MRI scans of the quality necessary for coregistration were not done.

We did not find differences between the global (gray) metabolic rates of patients with bulimia nervosa and normal comparison subjects. Consistent with the findings of Wu et al. (4), we observed a multiple regional, left-greater-than-right hemispheric asymmetry in the temporal lobes of patients with bulimia that was not observed in comparison subjects. Also consistent with the findings of Wu et al. we observed a right-greater-than-left frontal hemispheric asymmetry in the comparison group that was not present in the bulimic patients. In addition to the temporal lobe hemispheric asymmetries, we observed relative bilateral inferior temporal lobe hypermetabolism.

Orbitofrontal regions were analyzed to compare the results for our group of bulimic patients with those for patients with obsessive-compulsive disorder studied by Nordahl et al. (7) and Baxter et al. (8). There was no difference in mean regional cerebral glucose metabolism, nor was there a positive correlation between regional cerebral glucose metabolism and obsessive-compulsive disorder symptoms (according to the Maudsley Obsessive-Compulsive Inventory) in the orbitofrontal regions. Conversely, there were negative correlations between obsessive-compulsive disorder symptoms and orbitofrontal metabolism in the medial and left lateral orbitofrontal regions and a trend toward a negative correlation in the right lateral orbitofrontal region. This might lead one to believe that orbitofrontal regions may subserve more than one function. For example, although bulimic patients have obsessive thoughts, disinhibited eating behavior may be connected with lower orbitofrontal metabolism. This might effectively hide orbitofrontal increases connected with obsessive thoughts. Alternatively, orbitofrontal regions could be a biological determinant for impulse control rather than being responsible for the generation of obsessive thoughts (20).

A study of anorectic patients who have obsessive thoughts about food but do not impulsively binge might find elevated orbitofrontal regional cerebral glucose metabolism like that of patients with obsessive-compulsive disorder. This type of study was performed by Herholz et al. (21), but they did not report higher orbitofrontal metabolism; the orbitofrontal area was not analyzed distinctly from the prefrontal or frontal areas. If the orbitofrontal area were analyzed distinctly, this hypothesis could be more reasonably tested.

In addition to confirming the findings of Wu et al. (4) and Hagman et al. (5), we found regional mean hypermetabolism bilaterally in the inferior temporal lobes and hypometabolism in the right anterior lateral prefrontal cortical areas. Design and implementation differences between our study and that of Wu et al. and Hagman et al. may be responsible for the different regional metabolic findings. First, we scanned nearly twice the number of subjects (they scanned eight comparison subjects and eight bulimic subjects), which increases the statistical power of finding smaller but significant mean differences. Second, the scanner used in our study had a slightly finer resolution (5.2 mm versus 7.6 mm in plane, resolution full width half maximum). Finally, we believe that the empirical attenuation correction increases the validity of our orbitofrontal values. Orbitofrontal metabolic values are difficult to measure with a calculated attenuation correction due to the variable bone density in the skull. Empirically measuring the attenuation correction decreases the variability of the observed orbitofrontal metabolic rates by measuring and correcting for the individual bone density.

Although we did not observe a pattern characteristic of obsessive-compulsive disorder in our bulimic patients, we did observe patterns typical of depressed patients. Metabolism in left anterior and posterior lateral prefrontal cortical areas correlated negatively with

Hamilton depression scale scores. When the patients whose Hamilton depression scale scores were 15 or greater were considered separately, mean regional cerebral glucose metabolism values in the left anterior and posterior lateral prefrontal cortex were found to be significantly lower than those of comparison subjects. This is consistent with and adds another diagnostic group to the regional cerebral glucose metabolism findings of Baxter et al. (6) in their study of depression in affective disorders and obsessive-compulsive disorder.

Hagman et al. (5) reanalyzed the data from eight bulimic women that Wu et al. (4) collected and compared them with scans of eight age-matched depressed women. They did not observe lower mean metabolism in the right or left anterior lateral prefrontal cortex in either depressed or bulimic subjects than in a group of comparison subjects. They did not report correlations between these subjects' Hamilton depression scale scores and their left anterior lateral prefrontal cortex regional cerebral glucose metabolism. Due to the lower numbers of subjects per cell, compared with the data of Baxter et al. (6) and this study, we believe there was not enough statistical power in the study of Wu et al. (4) and Hagman et al. (5).

The patients in our study were inpatients whose eating behavior was closely controlled. At the time of the PET scan these patients had abstained from binge eating and purging for at least 3 weeks but not more than 5 weeks. Neither the frequency of their pre-abstinence binge eating nor their caloric intake correlated with prefrontal or temporal metabolism. The frequency of binge eating episodes did correlate positively with higher metabolism bilaterally in the posterior frontal area of plane A and in the right parietal area of plane A; however, none of these areas was found in the similar correlations of Hagman et al. (5). Likewise, none of the correlations of frequency of binge eating found in the study of Hagman et al. was observed in this study group. One might therefore infer that if there is a correlation between binge eating frequency and regional cerebral glucose metabolism, it is a state-dependent correlation, or one might infer that the correlations observed occurred simply by chance because we had no a priori hypothesis for this particular region.

Hagman et al. (5) suggested a study that might include patients with bulimia with varying degrees of mood disturbance in order to elucidate the significance of mood disturbance within the syndrome. Our study satisfies this request and leads one to believe that left anterior lateral prefrontal cortex hypometabolism varies with the depressive symptoms observed in bulimia but that temporal lobe hypermetabolism and asymmetries appear to be independent of the mood state.

Coping With the Threat of AIDS: The Role of Social Support

Jane Leserman, Ph.D., Diana O. Perkins, M.D., and Dwight L. Evans, M.D.

Objective: There has been relatively little clinical research on how asymptomatic HIV-positive men cope with the threat of AIDS. The present study was intended to 1) describe the coping strategies used by asymptomatic HIV-positive homosexual men, 2) examine the relationship of coping to dysphoria and self-esteem, and 3) explore how race and social support correlate with coping. **Method:** The study group was composed of 52 asymptomatic HIV-positive homosexual men. A group of 53 HIV-negative homosexual men was used for descriptive comparison. Data on coping, social support, dysphoria, and self-esteem came from self-report measures; depression was also determined by interviews with the Hamilton Rating Scale for Depression. **Results:** The authors found that 1) subjects primarily coped with the threat of AIDS by adopting a fighting spirit, reframing stress to maximize personal growth, planning a course of action, and seeking social support; 2) more helpless coping, less fighting spirit, and less personal growth were related to dysphoria and poor self-esteem, whereas denial was related to more depression, anger, and helpless coping; 3) satisfaction with one's social support networks and participation in the AIDS community were related to more healthy coping strategies (e.g., fighting spirit, personal growth); and 4) black subjects expressed more denial, more helplessness, and less social support. **Conclusions:** These results suggest that health professionals should encourage more adaptive coping strategies, help patients use existing sources of positive social support, and assist patients, particularly black patients, in finding community support networks.

(Am J Psychiatry 1992; 149:1514-1520)

Infection with HIV raises a wide spectrum of concerns and fears among infected individuals. Even before symptoms occur, those infected with HIV have concerns about future economic security; sexuality and disease transmission; rejection from family, friends, and lovers; and eventual ill health and death. Previous research has focused on psychiatric alterations associated with HIV-positive status, most notably depression and anxiety (1-5). The present study focused on how asymptomatic HIV-positive homosexual men cope with the threat of AIDS. Among seropositive men, we 1) examined the relationship of coping to dysphoria and self-esteem in order to determine the positive or negative aspects of various coping strategies and 2) explored how social support and race are related to cop-

ing. We also studied the coping strategies (e.g., fighting spirit, helplessness, denial) used by HIV-positive men and compared these strategies with those of seronegative comparison subjects.

Much has been written about the role of coping in buffering the psychological impact of stress and possibly altering the progression of disease (e.g., cancer, AIDS). In cancer patients, Greer et al. (6) found that fighting spirit and denial were associated with a better prognosis than was helplessness or stoicism. Regardless of whether coping has a direct role in HIV disease outcome, it may have an important role in preventing depression as the threat of AIDS becomes a reality for those who were previously asymptomatic. The following questions remain: 1) Which coping strategies indicate the most healthy adaptive pattern? and 2) What role does social support play in eliciting adaptive coping styles?

Coping generally refers to "the cognitive and behavioral efforts to manage specific external and/or internal demands appraised as taxing or exceeding the resources of the individual" (7). To our knowledge, however, there has been no agreement on or exhaustive list of cognitive and behavioral efforts or strategies that people use to deal with threats. Although it has been assumed that active strategies are good and that passive

strategies are bad, only a few studies have delineated the mental health correlates of a variety of coping styles in people with HIV infection. Among homosexual men coping with HIV-related illness, two studies (8, 9) showed that active-behavioral coping was associated with enhanced mood and self-esteem and that avoidance coping (denial) was related to greater total mood disturbance and lower self-esteem. One study (5) showed no significant association between active or avoidant coping and psychological distress. In cancer patients, passive and suppressive coping strategies were related to emotional distress, whereas active coping styles (e.g., confronting problems, sharing concerns) were associated with less dysphoria (10). Our determination of adaptive or healthy coping strategies has been based on the relationship of the coping measures to depression, tension, anger, and self-esteem.

Given that more active coping strategies indicate better adaptation, what is the evidence that social support may lead to more adaptive coping styles? Among HIV-infected homosexual men, social support was shown to correlate positively with active coping and negatively with avoidance (8, 9). Other studies of HIV-infected men have shown a clear relationship of social support to less mood disturbance (5, 11–14), less helplessness (14), and greater self-esteem (12). In addition, social support has been linked to less anxiety and depression in a variety of community samples (15, 16).

In the present study we extended the work of others by looking at the relationship of seven specific coping styles to several measures of dysphoria, self-esteem, and social support. We hypothesized that coping by maintaining a fighting spirit, planning, personal growth, and seeking social support would be related to positive affect and self-esteem, whereas denial and helpless coping would be associated with negative affect and self-esteem. Furthermore, we hypothesized that social support, as measured by a variety of indicators (e.g., support satisfaction, participation in the AIDS community), would be associated with more fighting spirit, planning, personal growth, seeking social support, and religious coping and with less helplessness and denial. In addition to these hypotheses, we explored possible race differences in social support and coping. Furthermore, to describe the seropositive men, we compared their coping strategies to those of seronegative comparison subjects, since the threat of AIDS is inherently more immediate for those infected with HIV.

METHOD

Subjects

We studied 105 homosexual volunteers: 52 asymptomatic HIV-positive men and a comparison group of 53 HIV-negative men. This group is part of the Coping in Health and Illness Project, a large, multidisciplinary, longitudinal study. The study was approved by our institutional committee for the protection of human

rights, and all subjects provided written informed consent. Subjects were recruited from North Carolina county health departments and through homosexual organizations, advertisements, and word of mouth.

The men were between the ages of 18 and 50 years and were required to have at least a 10th-grade education or a general equivalency diploma and to have spoken English as their primary language before the age of 12. All HIV-positive subjects were asymptomatic, without AIDS or AIDS-related complex (e.g., night sweats, herpes zoster, oral candidiasis, hairy leukoplakia, shingles, unexplained fever or diarrhea, and unexplained weight loss or fatigue in the presence of other symptoms) according to the Centers for Disease Control criteria. All subjects were further screened to exclude any individual with important medical illness, a recent operation, or a history of intravenous drug use as a risk factor for HIV exposure. These screening criteria were included for the neuropsychological and psychoimmune aspects of the larger study.

Procedure

Over 2 nights and days at an inpatient research center, the subjects underwent psychiatric, physical, neurologic, and neuropsychological examinations and several blood samples. On the first evening, before any testing, each subject completed a packet of self-report questions about coping.

Measures

Coping was assessed by means of the Coping in Health and Illness Project questionnaire with a modification of the COPE (17). The subjects were asked to indicate on a 4-point scale ("not at all" to "very much") how they "generally cope with, or handle the threat of getting AIDS." The subjects indicated their coping responses to items included in five of the 14 scales of the COPE: 1) planning (e.g., "I try to come up with a strategy about what to do"), 2) positive reinterpretation and personal growth (e.g., "I try to see it in a different light, to make it seem more positive"), 3) seeking emotional social support (e.g., "I try to get emotional support from friends or relatives"), 4) denial (e.g., "I pretend that it hasn't really happened"), and 5) turning to religion (e.g., "I seek God's help"). In addition, we added items to create two additional scales, helpless coping and fighting spirit. Items for these two coping measures were modified versions of items from Greer and Watson's coping questionnaire for cancer patients (18). To create indexes of helpless coping and fighting spirit, we ran a principal factor analysis with quartimax rotation for each index; quartimax was used because we wanted to find the factor structure of a set of items. Initially, 11 fighting spirit items and nine helpless coping items were analyzed (for both the 52 HIV-positive and the 53 HIV-negative homosexual men). Items loading (greater than 0.38) on the primary factor were retained, yielding nine fighting spirit items and eight helpless coping items.

^aAdjusted mean scores are from analysis of covariance with race and education controlled. Range of possible scores is 1 to 4.^bTwo-tailed p values; df=1, 101.

Cronbach's alphas for both the HIV-positive and HIV-negative men were checked to ensure reliability of the scales for both groups. The item scores were summed and divided by the number of items to create all coping indexes, which ranged from 1 to 4. Table 1 shows the intercorrelations among coping indexes and the substantial Cronbach's reliability coefficients on the diagonal of the matrix (ranging from 0.77 to 0.93).

Depression and dysphoric mood for the past week were assessed with the self-report Carroll Rating Scale for Depression (19), the Profile of Mood States (POMS) (20), and the interview-based Hamilton Rating Scale for Depression (21). Consensus psychiatric diagnoses were made by reviewing a structured diagnostic interview (modified Structured Clinical Interview for DSM-III-R) (22, 23) at a diagnostic conference. The Rosenberg Self-Esteem Scale (24), a 10-item evaluation of the subject's self-esteem, was also administered.

We assessed social support in several ways. The Sarason Brief Social Support Questionnaire (25) assessed the degree of satisfaction with people the subject counted on for social support or help (Cronbach's alpha=0.86). Social conflict was measured with a seven-item inventory used in the Multicenter AIDS Cohort

Study (unpublished 1989 paper by K. O'Brien et al.) in its coping and change survey. The social conflict scale (Cronbach's alpha=0.87) addresses the degree of conflict the individual has experienced in the past month with the people in his personal life (e.g., "Have you felt irritated or resentful toward people in your personal life?"). We also developed a six-item scale to measure participation in the AIDS community (e.g., belonging to AIDS support groups and organizations, socializing with HIV-positive people) (Cronbach's alpha=0.75).

Statistical Methods

To describe the coping strategies of the study group, we first compared the seropositive and seronegative subjects on the seven coping variables by using multivariate analysis of variance (MANOVA). Significant results from MANOVA (Wilks's lambda, $F=3.79$, $df=7$, 97 , $p=0.001$) allowed us to perform separate analyses of covariance on the coping measures, with serostatus as the independent variable and education and race as covariates (table 2). Education and race were controlled, since these variables were correlated significantly with both serostatus and coping. The assumption of parallel regression of the covariates was met. The probability values in table 2 are two-tailed.

The remaining analyses were performed only for the HIV-positive subjects. Pearson product-moment correlation (with two-tailed significance tests) was used to show the interrelationships among the coping measures (table 1). Principal factor analysis with varimax rotation was used to confirm the pattern of correlation among the coping indexes (with 0.38 as the cut-off for inclusion in a factor). Cronbach's alpha for each coping index indicates the reliability or internal consistency of each measure.

To examine the relationship between coping and measures of dysphoria, we performed multiple regression analyses with the dysphoria measures as the dependent variables and the coping variables run separately as independent variables, holding constant age, education, race, and months since the subject learned he was HIV positive. These background variables were chosen because they were significantly related to some

^bp<0.01, one-tailed test.

^cp<0.05, one-tailed test.

of the coping measures. They were controlled to rule out the possibility of spurious findings. Only race altered the relationships of some coping measures to dysphoria (regression coefficient change of 20% or more). Therefore, table 3 shows the partial correlations of coping with depression, tension, anger, and self-esteem, with race controlled. All tests are one-tailed.

We were next interested in testing the relationship of coping to social support variables: support satisfaction, participation in AIDS groups, and social conflict. Since only race (and not age, education, or time since the subject learned he was seropositive) was related to social support and coping variables, we determined partial correlations between support and coping variables, holding race constant. Since a few of the zero-order relationships were diminished when we controlled for race, the results of the partial correlation analysis are shown in table 4. All tests are one-tailed because of the testing of directional hypotheses. We will also report the zero-order correlation coefficients (two-tailed) for the correlations of race with the coping and social support variables, as well as partial correlations of race and coping when social support is held constant.

RESULTS

The HIV-positive subjects had a mean age of 30.0 years (SD=6.7) and an average education of 14.4 years (SD=2.5), and 76.9% (N=40) were white. The HIV-negative subjects had a mean age of 30.9 years (SD=6.9) and an average education of 15.9 years (SD=2.4), and 90.6% (N=48) were white. Since we were interested in race effects on psychosocial variables, we compared the background characteristics of the black and white seropositive subjects. Although the differences were not significant, the blacks had less education (mean=13.3 years, SD=1.9) than the whites (mean=14.7, SD=2.6) ($t=1.74$, $df=50$, $p=0.09$), and the blacks were younger (mean age=27.8 years, SD=3.9) than the whites (mean=30.7, SD=7.2) ($t=1.8$, $df=34$, $p=0.08$). Only two (16.7%) of the blacks met the DSM-III-R criteria for

lifetime drug dependence or drug abuse, compared to 19 (47.5%) of the whites ($\chi^2=3.65$, $df=1$, $p=0.06$).

Table 2 shows the means (adjusted for race and education) and standard deviations for the ratings of coping measures for the seropositive and seronegative subjects. Most subjects endorsed fighting spirit, personal growth, planning, and seeking social support and rejected helpless coping and denial. The seropositive subjects generally coped with the threat of AIDS with more fighting spirit, yet also more denial and helplessness, than did the seronegative comparison subjects.

Table 1 shows the pattern of intercorrelation among the coping measures in the HIV-positive subjects. Factor analyses of these scales confirmed the two-factor pattern of correlation shown in table 1 (two factors with eigenvalues above 1). The first factor (explaining 69% of the variance in the matrix) included fighting spirit, personal growth, active planning, seeking emotional social support, and, to a lesser extent, religious coping. These five indexes might represent more active or positive coping strategies. The second factor (explaining 31% of the variance in the matrix) included helpless coping and denial. Thus, subjects who felt helpless when confronting the threat of AIDS also tended to deny this threat ($r=0.48$,

$df=50$, $p=0.0004$). Denial and helplessness may represent more passive or negative coping responses.

Our next question was whether particular coping strategies were related to positive or negative affect (dysphoria) or to self-esteem. Overall the seropositive subjects scored relatively low on our depression measures (Hamilton Rating Scale for Depression: mean=4.69, $SD=4.79$; Carroll Rating Scale for Depression: mean=9.13, $SD=6.76$). Only five (9.6%) met the *DSM-III-R* criteria for a current major depression, although fully 21 (40.4%) had had major depression during their lifetimes. Table 3 shows the partial correlations of coping with depression, tension, anger, and self-esteem when race was controlled (race was the only covariate that altered the relationships of coping to dysphoria and self-esteem). The homosexual men who felt helpless about the threat of AIDS were significantly more depressed and tense and had lower self-esteem. Denial was also consistently associated with dysphoric states, particularly angry mood. The subjects with fighting spirit tended to be less depressed on all measures and had much higher self-esteem. Reacting to the AIDS threat by seeing it as an opportunity for personal growth was also significantly associated with less depression and with more self-esteem. Having plans to cope with the threat of AIDS was unrelated to all dysphoria measures, although it was related to better self-esteem. Finally, coping by seeking social support or by turning to religion was not significantly correlated with the dysphoria measures or with self-esteem.

Before analyzing the relationship between social support and coping, we were interested in whether there were race differences on the coping and social support measures. Blacks were more likely than whites to endorse the coping strategies of helplessness ($r=0.29$, $df=50$, $p=0.04$), denial ($r=0.33$, $df=50$, $p=0.02$), and turning to religion ($r=0.32$, $df=50$, $p=0.02$) and were less likely to seek emotional support ($r=-0.42$, $df=50$, $p=0.002$) to cope with AIDS. These race differences were not explained by age, education, or time since the subject learned of his serostatus. The races did not differ on the other coping indexes. Blacks' greater dissatisfaction with existing social support networks ($r=-0.28$, $df=50$, $p=0.05$) largely explained their greater feelings of helplessness (partial $r=0.13$, $df=49$, $p=0.36$) and somewhat explained their lower tendency to seek emotional support (partial $r=-0.29$, $df=49$, $p=0.04$).

Table 4 shows the relationship between social support measures and coping strategies when race was held constant. Satisfaction with support contributed to significantly less helpless coping, more fighting spirit, more personal growth, greater likelihood of seeking social support to deal with AIDS, and more turning to religion for help. Furthermore, participation in the AIDS community was associated with significantly more personal growth and a significantly greater tendency to seek emotional support as a way of coping with AIDS. Conflict in social relationships was unrelated to coping except that the subjects with more conflict were significantly less likely to seek social sup-

port when threatened by AIDS (partial $r=-0.33$, $df=49$, $p=0.02$).

Planning was unrelated to any social support variable except coping by using social support ($r=0.41$, $df=50$, $p=0.002$). Using denial was also not correlated with any social support variable. Denial was, however, related to anger, depression, helpless coping, and being black. In a regression model predicting denial, we found that being black ($\beta=0.26$, $t=2.21$, $df=47$, $p=0.03$), being angry ($\beta=0.35$, $t=3.02$, $df=47$, $p=0.004$), and feeling helpless about dealing with AIDS ($\beta=0.38$, $t=3.20$, $df=47$, $p=0.003$) explained 39% of the variance in denial.

DISCUSSION

A major finding of this study was that homosexual HIV-positive men can be characterized as coping with the threat of AIDS by adopting a fighting spirit, reframing stress to maximize personal growth, planning a course of action, and seeking social support. To a large extent, our study subjects scored low on denial and helplessness, and most did not have noteworthy depressive symptoms or current major depression. The low values on denial and helplessness may be due to the subjects' adaptive coping strategies, their asymptomatic status, the nature of subjects who volunteer for an HIV study, and/or the undesirability of admitting to helplessness. The high scores for fighting spirit and the low helplessness scores are consistent with findings from other research studies (8, 13). Interestingly, the HIV-positive subjects scored higher on fighting spirit, helplessness, and denial than did the HIV-negative men. Given that the threat of AIDS is more real and immediate to HIV-positive men, they may more actively mobilize all coping strategies.

We examined the relationship of coping strategies to each other and to measures of dysphoria and self-esteem to determine which coping strategies are associated with more healthy adaptation to HIV infection. Fighting spirit, personal growth, active planning, seeking emotional support, and, to a lesser extent, religious coping appeared to represent similar active or positive coping responses. Denial and helplessness appeared to represent passive and pessimistic coping strategies. As one might expect, helplessness was related to dysphoria and lowered self-esteem, whereas fighting spirit and positive growth tended to be correlated with favorable affect and better self-esteem. These findings support the use of strategies that are emphasized in stress management programs, such as fighting spirit and reframing stress through positive reinterpretation and personal growth. Those who cope with the threat of AIDS by more planning, seeking social support, or turning to religion appear not to be better or worse off with regard to dysphoric mood.

The relative merit or harm of denial (pretending HIV infection has not happened) is less apparent in the available literature. Whereas Greer et al. (6) found that denial had positive survival value in breast cancer

patients, studies in the psychological literature have tended to be less clear about the mental health implications of denial. In our group of HIV-positive homosexual men, it appears that underlying the denial of HIV-positive status were depression, feelings of helplessness, and anger. These findings are consistent with other studies of HIV-infected men (8, 9). Possibly, the HIV-positive individuals who feel overwhelmed by the threat of AIDS express this by more denial, depression, anger, and helplessness.

Finally, we were interested in whether social support is related to particular coping strategies. To a large extent, we found that being satisfied with one's social support networks and participating in the AIDS community were related to more healthy coping strategies (e.g., more fighting spirit, more personal growth, less helplessness). These findings are consistent with previous research (8, 9). Given the cross-sectional design of the present study, however, we cannot determine whether having strong social support leads to enhanced ability to cope with the threat of AIDS or whether those who cope effectively with stress are then better able to elicit social support. These relationships will be studied in our longitudinal follow-up of these subjects. It seems more likely that social support buffers some of the difficulties associated with the threat of AIDS and helps subjects maintain a positive and empowering approach to this disease. Socializing with other HIV-positive men and participating in AIDS support groups, the buddy program, and AIDS organizations may be other ways to help those with HIV infection adapt and perhaps grow from this experience. For homosexual men, who may receive less support from their families, these other sources of support may be critical. Establishing strong social support networks before the onset of HIV-related symptoms may help buffer the mental health consequences of this devastating illness.

The black subjects in our study tended to cope by means of more helplessness, denial, and turning to religion and by less seeking of social support. To some extent, this was due to less satisfaction with their social support networks. It seems that HIV-positive blacks, because they bear the stigma and isolation of race, homosexuality, and HIV infection, should be particularly targeted for social support interventions.

In conclusion, our findings suggest that 1) these subjects primarily coped with the threat of AIDS by adopting a fighting spirit, reframing stress to maximize personal growth, planning a course of action, and seeking social support, 2) more helpless coping, less fighting spirit, and less personal growth were related to dysphoria and poor self-esteem, 3) denial was related to more depression, anger, and helpless coping, 4) satisfaction with one's social support networks and participating in the AIDS community were related to more healthy coping strategies, and 5) black subjects experienced more denial, more helplessness, and less social support. These results suggest that health professionals treating HIV-positive patients should promote a fighting spirit and help patients reframe this health crisis as an opportunity

for personal growth and challenge. Patients who are coping by denial (pretending that HIV infection has not happened) may really be expressing helplessness, anger, or depression and thus may need psychological or psychiatric services. As noted previously (26), patient evaluations should include assessment of available family, friend, and other social support networks. Most important, professionals should encourage patients to use their existing sources of positive social support and should help patients, particularly black patients, find new supports in the community.

Psychopathology, Hypnotizability, and Dissociation

Edward J. Frischholz, Ph.D., Laurie S. Lipman, M.D., Bennett G. Braun, M.D.,
and Roberta G. Sachs, Ph.D.

Objective: The purpose of the study was to replicate and extend previous findings regarding the hypnotizability of different clinical groups. **Method:** The authors compared the differential hypnotizability of four psychiatric groups—patients with dissociative disorders (N=17), schizophrenia (N=13), mood disorders (N=13), and anxiety disorders (N=14)—and one normal group of college students (N=63). Hypnotizability was assessed by four different measures: the eye roll sign and the induction score of the Hypnotic Induction Profile, the Stanford Hypnotic Susceptibility Scale, Form C, and two self-ratings of hypnotizability. **Results:** As predicted, dissociative disorder patients had significantly higher hypnotizability scores on all measures than all other groups. Schizophrenic patients, on the other hand, had significantly lower scores than normal subjects on the eye roll sign and induction score but not on the other measures of hypnotizability. Some other unpredicted between-group differences were also found. Nevertheless, despite the between-group differences, the intercorrelations between the various hypnotizability measures within the normal group were very similar to those observed in the combined patient groups. **Conclusions:** The findings suggest that routine hypnotizability assessment may be useful in the differential diagnosis of patients with dissociative disorders. (Am J Psychiatry 1992; 149:1521–1525)

The relationship between psychopathology, hypnotizability, and dissociation has received increasing attention over the last decade (1–11). The major methodological focus of these reports has been on developing a better understanding of different kinds of psychopathology by studying the hypnotizability scores of different clinical groups. For example, because of the historical association between hypnotizability and dissociation, patients suffering from dissociative disorders or other psychiatric syndromes that have a hypothesized dissociative component were predicted to have significantly higher hypnotizability scores than normal subjects or patients with nondissociative conditions (1, 2, 4, 11, 12). In contrast, others predicted that patients with certain kinds of psychiatric illnesses, such as schizophrenia, should have significantly lower hypnotizability scores than normal subjects or other clinical groups (9, 11, 13). A growing number of studies have tested each of these predictions (4, 9, 14). Unfortunately, no clear pattern of findings has emerged, and

empirical support for each of these predictions appears to be moderated by both the type of clinical disorder studied and the type of hypnotizability scale employed (4, 9, 14). Therefore, before further studies are carried out, it would be wise to consider what types of clinical patients are expected to be more or less hypnotizable than normal subjects and what types of hypnotizability scales are most likely to detect significant differences between these groups.

There are many different methods for measuring individual differences in responsivity to hypnosis, such as the Barber Suggestibility Scale (15), the Stanford Hypnotic Susceptibility Scales (16–18), the Hypnotic Induction Profile (11, 19), and various self-rating procedures (20). While scores on these tests correlate positively (21, 22), the intercorrelations are not high enough ($r=0.6$ – 0.7) to consider these different instruments as interchangeable measures. Hence, some clinical groups may score significantly higher or lower than normal subjects on one type of hypnotizability measure but not on another.

What type of clinical groups are expected to be significantly more or less hypnotizable than “normal” subjects? (Note that most studies have assumed that college students are an appropriate normal comparison group.) Historically, patients suffering from dissociative disorders (e.g., multiple personality disorder or psychogenic fugue) have been considered by most to be significantly more hypnotizable than normal subjects

(23, 24). This prediction has received some empirical confirmation. For example, Bliss (1) has reported that two different samples of patients suffering from multiple personality disorder had significantly higher mean scores on the Stanford Hypnotic Susceptibility Scale, Form C (18), than normal subjects. Unfortunately, no data were reported on the reliability of the diagnosis of multiple personality disorder and no other types of dissociative disorder patients were studied.

Two other types of clinical groups that have been hypothesized to have a dissociative component to their psychiatric symptoms—patients suffering from post-traumatic stress disorder (PTSD) (25–27) and phobic patients (2)—have also been studied. Hence, these kinds of patients were also expected to have significantly higher mean hypnotizability scores than normal subjects. For patients with PTSD, this prediction has been confirmed in two separate studies. For example, Stutman and Bliss (27) found that patients with PTSD had a significantly higher mean score on the Stanford Form C than normal subjects. Spiegel and associates (26) reported a similar finding with the Hypnotic Induction Profile. However, no clear pattern of findings has emerged regarding the higher hypnotizability of phobic patients. For example, several studies have found that phobic patients were more hypnotizable than normal subjects (2, 28–31), others found no significant between-group differences (32, 33), and another study observed that phobic patients were significantly less hypnotizable than normal subjects (34).

Finally, other clinical disorders that have been hypothesized to have a dissociative component are conversion disorders, histrionic personality disorders, and mixed personality disorders. However, only one study has found that patients with these kinds of diagnoses have significantly higher mean hypnotizability scores than normal subjects (E.J. Frischholz et al., unpublished 1991 paper).

On the other hand, it has been hypothesized that schizophrenic patients are significantly less hypnotizable than normal subjects because of some type of attention or concentration deficit (11). However, this finding appears to obtain only for scores on the Hypnotic Induction Profile (8, 9, 11; unpublished 1991 paper of E.J. Frischholz et al.), not for the Stanford Form C (4). The study by Pettinati et al. (8) is particularly interesting in this regard, since both the Hypnotic Induction Profile and the Stanford Form C were employed. In that study, schizophrenic patients had significantly lower Hypnotic Induction Profile scores than normal subjects but mean scores similar to those of normal subjects on the Stanford Form C. This finding was obtained despite a correlation of 0.55 between scores on the Hypnotic Induction Profile and Stanford Form C. Finally, one recent study (7) reported that the mean Hypnotic Induction Profile score for six schizophrenic patients was not significantly different from the reported mean score for normal subjects.

Collectively, these findings suggest that further research is necessary to document what types of psychi-

atric syndromes are characterized by hypnotizability that is higher or lower than normal. Such research should study groups that are expected to have hypnotizability scores that are higher or lower than those of normal subjects, and multiple measures of hypnotic responsiveness should be employed. Furthermore, the clinical groups should be independently and reliably diagnosed according to standardized criteria, and the interrater reliability of the various hypnotizability scores should be demonstrated.

METHOD

The purpose of the present study was to replicate and extend previous findings regarding the hypnotizability of different clinical groups. Five groups were studied: dissociative disorder patients, schizophrenic patients, anxiety disorder patients, mood disorder patients, and college students (i.e., "normal" subjects). All subjects were volunteers in experiments that required the routine administration of the Hypnotic Induction Profile, Stanford Form C, and two self-ratings of hypnotizability taken immediately after the objective scales were given. All patients in the four clinical groups were independently diagnosed according to *DSM-III* and *DSM-III-R* criteria by both a psychiatrist and a clinical psychologist. Patients were included in the present study only if both mental health professionals agreed on their diagnosis. Hypnotizability examiners were unaware of the patients' diagnosis at the time of testing.

Seventeen patients with a primary diagnosis of dissociative disorder were tested. Seventy-one percent ($N=12$) had a diagnosis of multiple personality disorder, while the other 29% ($N=5$) had a diagnosis of dissociative disorder not otherwise specified. All of these patients were women, and their mean age was 35.1 years ($SD=9.7$). Ten patients were taking psychiatric medication.

All 13 schizophrenic patients were diagnosed as schizophrenic, paranoid type. Seventy-seven percent ($N=10$) were men, and the mean age was 37.6 years ($SD=8.0$). All of the patients were taking antipsychotic medication.

Of the 14 subjects in the anxiety disorder group, 7% ($N=1$) had a diagnosis of generalized anxiety disorder, 14% ($N=2$) had a diagnosis of simple phobia, 14% had a diagnosis of agoraphobia without panic disorder, 29% ($N=4$) had a diagnosis of panic disorder with agoraphobia, and 36% ($N=5$) had a diagnosis of panic disorder without agoraphobia. Fifty percent of the subjects were men, and the mean age was 33.9 years ($SD=8.1$). Nine patients were taking antianxiety medication.

Of the 13 subjects in the mood disorder group, 31% ($N=4$) were suffering from major depression (single episode), 39% ($N=5$) had recurrent major depression, 23% ($N=3$) had bipolar disorder, and 7% ($N=1$) had a dysthymic disorder. Ninety-two percent ($N=12$) of the group were women, and the mean age was 45.6 years ($SD=10.4$). Eight patients were taking antidepressant medication.

^aMeans that do not share the same column subscript are significantly different from one another at the 0.05 level (Duncan's multiple range test).

Sixty-three college undergraduates served as the normal comparison group. Sixty percent (N=38) were male, and the mean age was 20.9 years (SD=3.7).

RESULTS

Interrater Reliability of Hypnotizability Scores

Different examiners readministered the Hypnotic Induction Profile and Stanford Form C to 31 subjects from the four clinical groups within a week's time. Relative interrater reliability coefficients were computed using an intraclass correlation model discussed by Shrout and Fleiss (35). The interrater reliability was 0.95 for the eye roll sign score of the Hypnotic Induction Profile, 0.90 for the induction score of the Hypnotic Induction Profile, and 0.95 for Stanford Form C scores. Collectively, these findings indicate that hypnotizability scores on each of the two different scales were highly reliable over both examiners and a week's time.

Hypnotizability Scores Among Clinical and Normal Groups

The means and standard deviations for each hypnotizability measure cross-classified by normal/clinical group are presented in table 1. A two-way multivariate analysis of variance (MANOVA) was first computed with hypnotizability scores as the dependent variables and medication status (medication versus no medication) and clinical diagnosis (dissociative disorder, anxiety disorder, and mood disorder) as the independent variables. The results indicated a significant main effect for clinical diagnosis ($p < 0.01$). However, no significant effects for medication status or the medication status/clinical diagnosis interaction were observed. Therefore, a one-way MANOVA was used to compare the differences between mean scores for the various clinical/normal groups. This analysis indicated that significant differences between groups were present ($F = 4.37$, $df = 20$, 438 , $p < 0.001$). Individual analyses of variance and special contrasts were then calculated to further clarify the nature of these differences.

It is clear from the findings presented in table 1 that dissociative disorder patients had significantly higher mean scores on every measure of hypnotizability than all other clinical and normal groups. In contrast, schizophrenic patients had significantly lower mean eye roll scores and induction scores than normal subjects and anxiety disorder patients, but they did not have significantly lower scores on the Stanford Form C or either of the self-ratings of hypnotizability. Finally, although mood disorder patients had significantly lower mean eye roll scores than normal subjects, they did not have significantly lower mean induction scores than normal subjects, as has been found in previous studies (8, 9, 11; unpublished paper of E.J. Frischholz et al.).

Correlations Between Hypnotizability Measures

The correlations between the various hypnotizability measures within the normal group (N=63) and combined clinical groups (N=57) are presented in table 2. All of the hypnotizability measures intercorrelated positively (range of r values=0.25–0.78) and were significant at the 0.05 level (two-tailed). In addition, the correlations between measures were not significantly different from one another in comparisons of the matrices for the normal group (average $r = 0.54$) and combined clinical groups (average $r = 0.53$). However, it is clear that the eye roll score correlated lower with the other measures of hypnotizability. Hence, one can conclude that the eye roll probably does measure the same thing as the other measures of hypnotizability.

DISCUSSION

The findings of the present study suggest that routine hypnotizability assessment may be useful in the differential diagnosis of patients with dissociative disorders from normal subjects and patients with other types of psychopathology. In spite of the variability in the specificity and sensitivity of the hypnosis measures, dissociative disorder patients were observed to have significantly higher hypnotizability scores on various measures than all other groups had. This is consistent

with the previous findings reported by Bliss (1) and the classic clinical observations of Janet (23), Prince (24), and contemporary investigators (5, 11). In addition, contrary to the opinion expressed by Frankel (12), the findings support a theoretical and empirical relationship between the constructs of dissociation and hypnotizability.

The findings also provide support for the contention (11) that schizophrenic patients have significantly lower eye roll sign and induction scores than normal subjects but not lower scores on the two self-ratings of hypnotizability (self-rating induction measure and self-rating Stanford Form C) or the Stanford Form C scale. Again, these results replicate the findings of most other studies (4, 8, 9, 11; unpublished 1991 paper of E.J. Frischholz et al.; *DSM-III-R*) but not the methodologically flawed, small sample study reported by Murray-Jobsis (7). Interestingly, this finding was observed despite significant intercorrelations between eye roll sign and induction scores and the other measures of hypnotizability. For example, induction scores correlated ($r=0.72$) with Stanford Form C scores in the combined clinical groups. Yet induction scores were sensitive to differences between schizophrenic patients and normal subjects, while Stanford Form C scores were not. Further research is necessary to determine why eye roll sign and induction scores, despite their significant intercorrelations with other measures of hypnotizability, significantly discriminate between normal subjects and schizophrenic patients.

Surprisingly, mood disorder patients did not have significantly lower induction scores than normal subjects did, as they have been found to do in other studies (4, 8; unpublished paper of E.J. Frischholz et al.). However, the induction score for mood disorder patients in the present study (mean=5.13) was not significantly different from that observed in the study by Pettinati et al. (8) (mean=5.49). This suggests that the failure to find a significant difference between mood disorder patients

and normal subjects in the present study may be due to a smaller sample size, since the differences are in the predicted direction. Consistent with the findings of other studies, mood disorder patients did not have significantly different mean Stanford Form C scores than normal subjects had (8).

Similarly, anxiety disorder patients in the present study did not have significantly different hypnotizability scores than normal subjects. However, this may be because only 14% of the patients in this group had a phobic diagnosis. Phobic patients have been found to have significantly higher hypnotizability scores than normal subjects in some studies (2, 28–31) but not in others (32–34). In addition, none of the anxiety disorder patients in the present study was suffering from PTSD. Patients with PTSD have been observed to have significantly higher mean hypnotizability scores than normal subjects in other studies (26, 27). Further research is necessary to determine what type of anxiety disorder patients have significantly higher or lower hypnotizability scores than normal subjects.

As has been found in previous investigations (36–38), medication status did not appear to moderate differences in hypnotizability between the clinical groups in the present study when it was possible to test this hypothesis. It was not possible to test the hypothesis in the schizophrenic group because all of the patients were taking antipsychotic medication. However, medication status has not been found to significantly affect the hypnotizability scores of schizophrenic patients in other studies (36–38).

Collectively, the results of the present study highlight the clinical and theoretical utility of studying hypnotizability differences between various normal and abnormal groups and between the choice of hypnotizability measures. Undoubtedly, some groups are consistently more or less hypnotizable than others, although these relationships appear to be moderated by the type of normal or abnormal group studied and the type of hyp-

notizability scale employed. Furthermore, issues of reliability of diagnosis and hypnotizability score must also be addressed before any firm conclusions can be drawn. Nevertheless, the findings of the present study and previous investigations clearly indicate that dissociative disorder patients are more hypnotizable than normal subjects or other clinical groups.

A Historical Perspective on the Role of State Hospitals Viewed From the Era of the "Revolving Door"

Jeffrey L. Geller, M.D., M.P.H.

***Objective:** By focusing on the functioning of a state hospital throughout its existence, the author provides a historical perspective on the nature and causes of "revolving door" admissions. **Method:** Northampton State Hospital was chosen as a prototype, and data on characteristics of patients and patterns of hospital utilization were analyzed from three 10-year periods: 1880–1889, 1930–1939, and 1980–1989. The data for the first two time periods came from the hospital's admission and discharge logbooks and its annual reports; the material for the most recent decade was obtained from unpublished yearly reports generated by the hospital's medical records department. **Results:** The hospital operated very differently in each of the decades analyzed, but only in the 1980s was recidivism a major finding. This was not, as has often been thought, due to problems or populations unique to the state hospital in the 1980s nor to the fact that in earlier eras the state hospital rarely discharged patients. The once-large asylum has been replaced by a facility rapidly admitting and discharging patients, many of whom have accumulated more than 10 lifetime admissions, in a pattern of care not previously noted. **Conclusions:** State hospitals have functioned in different yet questionable ways throughout their history. Their current role of providing a revolving-door pattern of care to a considerable population is rooted in a contemporary shift in ideology. This role for state hospitals appears to make no more sense than did their earlier role as neglected and neglectful asylums, and it should be reevaluated.*

(Am J Psychiatry 1992; 149:1526–1533)

The literature has given them a multitude of labels—"recidivists," "revolving-door patients," "patients who return," "patients with frequent rehospitalizations," "heavy users," "patients with repeat admissions," "patients with recurrent psychiatric hospitalizations"; service providers experience them as legion; and the resources required for meeting their needs can be enormous. These are the persons with serious and persistent mental illness who have gone back and forth between public sector inpatient settings and the community in a pattern of care (or lack of care) often referred to as an unfortunate and unexpected consequence of deinstitutionalization.

Recidivism in contemporary public sector psychiatric settings can be viewed as a byproduct of clashes between two competing ideologies and their resultant clinical practices. The two ideologies are paternalism and autonomy. The competing loci of care and treat-

ment are the state hospital and the community. The battlefields are the allocation of resources to each and the statutes that determine who goes where. The casualties of this clash are the patients. And the unfortunate foot soldiers are the staffs, be they in state hospitals, community mental health centers, or any community program.

While recidivism appears to be uniquely contemporary, the tensions I have mentioned are not at all peculiar to our era. The issues thought to contribute heavily to the phenomenon of recidivism can be found clearly described in nineteenth-century publications. For example, on the issue of paternalistic commitment versus autonomy in the community, note the following from an 1883 issue of the *Alienist and Neurologist*: "We owe the harmless lunatic a duty to save him from perpetual lunacy if we can. To leave him wholly to himself, even though he hurts no one, is not always kind. Such a course endangers incurable chronicity, and this is cruel to him" (1).

On the threshold for determining dangerousness, note this from the same publication in 1883: "[If] unreasonable and unjust obstacles were not every day thrown in the way of committing the insane to the asylums whose care and treatment is their due, and whose

restraint is their right and the community's protection, murder by sane lunatics would be less frequent. Suppress the liberation epidemics" (2).

On the conditions of state hospitals, note these remarks from an 1885 issue of the *American Journal of Insanity*: "[Danvers State Hospital] has been a disgrace to the Commonwealth . . . One to two hundred patients have been obliged to occupy beds placed upon the floors . . . , personal privacy has been interfered with, . . . attendants and physicians have been wearied . . . [It is] 'a convenient dumping ground for all cases of degenerative nervous diseases attended with mental failure' which are disagreeable to care for elsewhere or whose care elsewhere costs more than at the asylum" (3).

Public sector inpatient recidivism is not simply a fall-out from current difficulties in providing care and treatment to persons with serious and persistent mental illness, because many of these difficulties existed before there appears to have been widespread recidivism. The revolving door is a phenomenon of the current ideologies that are the underpinnings of deinstitutionalization and the resultant role assigned to the state hospital.

Recent overviews of the policy of deinstitutionalization have dissected in great detail the ideologies and economics of deinstitutionalization, but they have not paid sufficient attention to the historical and contemporary role of the state hospital (4-6). One manner in which to understand the past roles and current functioning of state hospitals, and how these fit into the deinstitutionalization phenomenon, is to examine recidivism. Such an examination should help focus the debate about the future role of the state hospital.

To this end, I have used one state hospital, Northampton State Hospital, as the prototype and present data from three decades within 100 years. I chose this hospital because it has been in the vanguard of "second-generation deinstitutionalization" (7, 8) and the focus of considerable study. The data for this analysis came from the annual reports and admission/discharge log-books of Northampton State Hospital for the decades 1880-1889 (9, 10) and 1930-1939 (11-13) and from unpublished annual reports generated by the medical records department of the hospital for 1980-1989. The information on the nineteenth-century recidivists discussed in this article comes from patient and court records.

1880-1889

In the 1880 census of the United States, there was one insane person to every 545 inhabitants, or 91,997 insane persons. In 1886 there were 121 asylums (public and private), with at least one state institution in each of the 38 states except Vermont and Delaware, and 61,411 patients were treated in those asylums by medical staffs that totaled 377 physicians. Most of the states were struggling under the financial constraints of caring for the insane, particularly because of the increasing demands of chronic cases (14). There was excitement

about the "unparalleled progress" in psychiatry that allowed for a "scientific and positive basis for treatment in many cases of insanity which before was unattainable" (14). New medications abounded, violence on wards with refractory patients was diminishing, use of seclusion and restraint was decreasing, unlocked wards were common, occupational therapy was highly valued, and individual treatment plans were a "keynote of progress" (14).

It is within this climate that the functioning of Northampton State Hospital yielded the data presented in the first columns of tables 1 and 2. A closer look at 1 year is worthwhile. In 1886, the first year following the retirement of its illustrious superintendent, Pliny Earle, Northampton State Hospital had a year-end census of 491 patients. Edward Nims, the new superintendent, noted that 1886 was unusual in that the number of admissions was greater than it had been in previous years, including 25 patients transferred from Danvers Lunatic Hospital because of overcrowding there. Nims also noted a decrease in census due to the removal of 33 chronic patients to almshouses and 12 patients to family care, to be supported there, at the same cost as if they had been in the hospital, by the Board of Lunacy and Charity. Patients in the hospital worked at the farm, kitchen, sewing room, laundry, mattress room, ornamental grounds, stable, bakery, boiler room, carpenter shop, and wards. Indeed, the patients' labor was integral to the functioning of the hospital, as there were but 74 persons employed there; the personnel budget was \$28,969.39.

In 1886 there were 176 persons (80 male and 96 female) admitted for a total of 183 admissions; during the year seven persons were admitted twice. Of the 135 persons admitted for the first time, eight were less than 20 years of age and eight were over 60 years old. Of all persons admitted, the most common causes of insanity were (in decreasing order of frequency) intemperance, ill health, overwork, epilepsy, and masturbation. The admission diagnoses were mania (N=117), dementia (N=27), melancholia (N=22), epilepsy (N=11), general paralysis of the insane (N=4), inebriate (N=1), and no insanity (N=1).

In 1886 there were 168 discharges, which included 26 patients who died. Of the other discharges, 29 patients were recovered, 10 much improved, 59 improved, 43 unimproved, and one not insane. Of the 29 patients who recovered, 23 were hospitalized less than 1 year; of these, 13 were hospitalized less than 3 months. The 26 deaths included 16 patients who died of chronic diseases, eight who died of acute disorders (two of them of exhaustion from mania), and two who died of old age. Fourteen who died had been hospitalized less than 1 year, and 17 were more than 50 years old.

Finally, it is worth noting that the 1886 total expenditures for Northampton State Hospital were \$94,851.91, approximately \$3,000 less than the total receipts.

During the decade 1880-1889, Northampton State Hospital had a stable mean census of 466 (SD=14). The

hospital's admissions numbered about one-third of its census, so that the turnover rate for a bed was every 3 years. First admissions accounted for three-quarters of all admissions, and most admissions were of persons between 20 and 60 years of age. Few persons accumulated high numbers of lifetime admissions. Only eight persons had had more than five lifetime admissions by 1889; two of these individuals had had more than 10 admissions. While patients who were discharged as recovered had comparatively short stays, 81% of the patients at the year-end census had stays in excess of 1 year. Twenty-one percent of the discharges were accounted for by deaths. This group was a mixture of long-stay patients and those with shorter stays; a majority were over 50 years old. While the hospital fulfilled many functions during the decade—it was both an acute care facility and a long-term care facility—it was not a repository for geriatric patients, it did not keep patients whose improvement allowed their discharge, and it did not have a revolving-door population.

1930-1936

In 1936 there were 523 psychiatric hospitals in the United States, which provided care to 566,482 patients. Of these hospitals, 172 were state hospitals ranging in size from less than 1,500 patients (N=45) to over 6,000

patients (N=3). Medical staff coverage ranged from one physician for 125 patients to one for 1001 (15, 16). State hospitals were thought to be greatly improved (16, 17), but overcrowding (18) and political interference (19, 20) were major problems. Training and research were encouraged at state hospitals (21, 22), as was the use of the *New Standard Nomenclature of Diseases* (23).

Treatments in use in hospitals included rest (24), continuous baths (24) and wet packs (25), insulin coma and metrazol-induced convulsive therapy (26, 27), irradiation (28), sodium Amytal (29), and psychotherapy (16, 30). There were calls for community care (31) and for general hospital psychiatry wards (24).

In 1930 Massachusetts was expending approximately 20% of its annual budget for the care of mental patients (32). Northampton State Hospital was one of 13 state hospitals devoted to the care of persons with mental disease (33). The data for Northampton State Hospital from 1930 to 1939 are presented in the second columns of tables 1 and 2. An analysis of 1 year in detail shows that in 1936, Northampton State Hospital was undergoing expansion through construction projects under the WPA but nonetheless was experiencing overcrowding. High local unemployment allowed for a good caliber of persons to be employed as attendants. New treatments included malaria treatments for patients with neurosyphilis and sodium Amytal for catatonic patients.

The year-end census of 2,229 patients (1,028 male

^aNumbers declined over the decade.

and 1,201 female) included 1,871 patients in the hospital and 358 on visit. The major diagnostic categories of the patients in the hospital were dementia praecox (20%), psychosis with cerebral arteriosclerosis (8%), mental deficiency (7%), manic depression (6.5%), psychosis secondary to alcohol (6%), involutional psychosis (5%), CNS syphilis (4.5%), and senile psychosis (4.5%). Four hundred thirty-three of the year-end census patients represented readmissions; 268 (62%) of these were diagnosed as having dementia praecox.

In 1936 there were 619 admissions, eight of which were voluntary. The diagnostic distribution of these admissions was similar to that of the year-end census except that the diagnoses of psychosis with cerebral arteriosclerosis and psychopathic personality were a much higher percentage of the admissions than of the year-end census. Five hundred ten (82%) of the admissions were first admissions. The age distribution was significant in that 33% of the patients with first admissions were over 60 years of age. Nineteen percent of them were over 70 years old, and 98% of these had either psychosis secondary to cerebral arteriosclerosis or senile psychosis. Of all the patients who returned from visit status in 1936, only 58 had been out of the hospital for more than 1 month.

There were 568 discharges—351 to the community, 64 to other mental hospitals, and 153 representing patients who died. Of the discharges to the community, 65 (19%) of the patients had recovered, 211 (60%) were improved, 32 (9%) were unimproved, and 43 (12%) were without psychosis. Of the 147 patients who died in the hospital, 75 (51%) were more than 70 years of age. Of these, 82% had a primary psychiatric diagnosis of either psychosis secondary to cerebral arteriosclerosis or senile psychosis. Of the 83 patients who died with one of these two diagnoses, 38 (46%) had been hospitalized less than 4 months and 56 (67%) had been hospitalized less than 1 year.

In summary, during the decade 1930-1939, Northampton State Hospital had a census that increased by 40%, and the census was more than 2,000 patients from 1933 on. The mean number of admissions for the decade—575 (SD=58)—represented one-quarter of the census; hence the turnover rate for a bed was once every 4 years. Seventy-nine percent of all admissions were first admissions. Of these, 30% were of persons over the age of 60 and 15%-20% were of persons over 70 years of age. Almost all the patients admitted who were over 70 years old had psychosis secondary to either cerebral arteriosclerosis or senility. Of the mean of 508

(SD=85) discharges each year, an average of 32% were due to death. Many of those who died were older patients, most of whom had been hospitalized a comparatively short time. The patients who remained in the hospital did so for progressively longer times, so that by 1939 the mean length of stay of all first-admission patients in the hospital at year end was 8.42 years and of all readmitted patients was 8.76 years. Northampton State Hospital continued to admit and treat persons with serious and persistent mental illness—more than one-half of its year-end census who were readmitted patients had dementia praecox. But the facility had become one to which elderly, debilitated, senile individuals were sent, often to die within a year of their admission. There is no indication that many patients had frequent admissions and discharges; only three patients admitted during this decade had 10 or more lifetime admissions.

1980–1989

In 1984 a point-in-time census of all state and county mental hospitals in the United States indicated that there were 118,647 patients, which was 79% below the peak census of 558,922 patients recorded in 1955. Some states had decreased their public mental hospitals' census by more than 90% (4).

In 1986 there were 3,039 facilities providing inpatient services, of which 285 were state and county mental hospitals. These public hospitals accounted for 21.6% of the 2,055,571 total inpatient care episodes. Three-quarters of all patient care episodes at state and county mental hospitals were inpatient care episodes (34). By 1990 services for persons with serious mental illness were described as a "disaster," and deinstitutionalization was labeled a "hoax" (5). More persons with serious and persistent mental illness were in jails, prisons, or public shelters and on the streets than were in public mental hospitals (4).

During the 1980s Massachusetts' expenditure for mental health and retardation services increased by \$543 million, or 150%, from 1980 through 1988 (Massachusetts State Senate Committee on Ways and Means, Fiscal Year 1990 Budget Recommendations, June 1989). During this decade Northampton State Hospital, being the beneficiary of a federal court consent decree mandating treatment in the least restrictive suitable alternative (7), entered the forefront of deinstitutionalization. During the first 10 years the decree was in effect (1978–1988), Northampton State Hospital discharged *every* patient who had been in the hospital on the day the decree was signed (8). Data describing Northampton State Hospital in the 1980s are shown in the third columns of tables 1 and 2. From 1980 to 1989 the Northampton State Hospital census fell by 54%, and admissions decreased by 36%. Throughout the decade only 30% of all admissions were first admissions. The turnover rate of a bed at the hospital was approximately 5 times per year. Virtually all discharges were to commu-

nity settings, and the number of deaths (including deaths in general hospitals shortly after discharge) never constituted more than 0.5% of the number of discharges. Almost 95% of all discharges were after stays of less than 1 year, and the mean length of stay of discharged patients decreased by 84% throughout the decade.

The length of stay of patients in the hospital at the year-end census decreased dramatically. The mean length of stay of all first-admission patients decreased by 98%, from 14.4 years to 87 days. In 1988 no first-admission patient in the hospital had been there as long as 1 year. While patients in the hospital had shorter stays, a progressively greater percentage of them had had prior admissions, and the number of patients with 10 or more prior admissions increased annually.

A more detailed analysis of 1 year's data shows that in 1986, the year-end census of Northampton State Hospital was 226 patients (142 male and 84 female). Of these, 209 (92%) were in the hospital, 15 (7%) were on visit, and two (1%) had escaped. The length of stay in this year-end census ranged from 1 day to 23.5 years, with 9% of the population on the census less than 1 week, 29% less than 1 month, 45% less than 3 months, and 79% less than one year. In the year-end census there were 12 patients (5%) over the age of 65 years; half of these had stays of less than 6 months. A point-in-time study showed the diagnostic mix of patients in the census to be schizophrenia, 54%; affective disorder, 17%; organic brain syndrome, 8%; mental retardation, 4%; and all other diagnoses, 18%.

In 1986 there were 864 admissions (523 male and 341 female patients). Of these, 74 (9%) were less than 21 years of age, and 30 (4%) were more than 65 years old. The 864 admissions were accounted for by 655 different patients. One hundred forty patients had more than one admission in 1986. The mean length of stay of this group was 37 days, with a mean length of time between admissions of 70 days. The highest number of admissions that occurred in 1986 for any one patient was 13; this patient had accumulated 83 lifetime admissions over the 10-year period ending in 1986.

There were 823 discharges in 1986. Of these, 60% occurred after stays of less than 1 month, 81% after less than 3 months, and 93% after less than 1 year. Three patients died, all of whom were 75 years old or older; their lengths of stay were 4 years, 7.5 years, and 57 years.

COMPARISON OF THE THREE DECADES

From tables 1 and 2, a comparison of the operation of Northampton State Hospital in the 1880s, the 1930s, and the 1980s can be made. This compilation shows that the state hospital functioned very differently at each of these periods. During the 1980s, unlike before, it was a shrinking facility, with ever shorter lengths of stay. It no longer admitted many elderly infirm patients, as it had in the 1930s, and it had discharged much of the preexisting geriatric population; hence there were very few deaths. This difference in the death rate means

that a much higher percentage of patients discharged each year were potential readmissions, since deceased patients can obviously not be readmitted. But the difference in the death rate does not in and of itself account for the difference in the recidivism rate. If the facility had been operating in the 1980s as it had earlier, there would not have been as dramatic a difference in the ratio of admissions to census as there was. If anything, the higher death rates in the two earlier time periods would lessen this difference. More and more of the admissions were accounted for by patients with prior admissions. Further, individual patients accrued successively more admissions, in a pattern of care not previously noted in the 1880s or the 1930s.

During the 1980s the proportion of patients in the hospital at the year-end census who had 10 or more lifetime admissions ranged from 4.2% to 22.7% and averaged 14%. The number of patients with 10 or more admissions during the first 50 years of operation of Northampton State Hospital (1858–1908) numbered two. They were brother and sister. It is instructive in this historical review to provide a brief account of the two patients whose pattern of use foreshadowed modern trends of recidivism.

TWO NINETEENTH-CENTURY RECIDIVISTS

Case 1. Ms. A was a 40-year-old single woman living in the family home at the time of her first admission to Northampton State Hospital in 1867. She had had attacks of insanity of short duration for 12 years before her first admission. A younger sister had been briefly hospitalized at Northampton State Hospital 2 years earlier. Ms. A's family history revealed that the mother and several of the mother's siblings had been deemed insane.

Between 1867 and 1886 Ms. A was involuntarily admitted to Northampton State Hospital 17 times. Her mean length of stay for the first 15 admissions was 80 days (range=26–169 days), and her community tenure between admissions ranged from 13 days to 934 days.

Over the course of her first 16 admissions, Ms. A was discharged as recovered 12 times, much improved once, improved twice, and with no result noted once. Her illness was characterized by "sudden relapses of irregular intervals" and "sudden apparent recoveries." Her presentation was most often an attack of mania, including such symptom descriptions as "very noisy and talkative and destructive" (1876), "highly excited, talks vociferously" (1883), and "wild and excited and irrational in conversation" (1883). Less often she was described as depressed, and on one occasion she attempted suicide by drowning. There was little mention of interventions during these admissions, but those that were discussed included confinement in a "harness," "alternatives and tonics," "sulphoral," and work in the sewing room.

While the hospital records made no mention of it, the court commitment papers indicated that during Ms. A's sixteenth admission her father died. It was to his care that she had returned at each prior discharge. Ms. A's sixteenth hospitalization lasted 415 days, much longer than any prior stay. Her siblings, without their father, tried once to have her live at home. She was returned to Northampton State Hospital after 2 months for her seventeenth and last admission in 1886. With

no family to provide care for her in the community, she could not be discharged. She remained in Northampton State Hospital 10.4 years, demonstrating intermittent manic episodes during that decade. She died in the midst of one such episode. Her record ends: "She died of exhaustion."

Case 2. Ms. A's brother was a 27-year-old single man living at home when he was admitted for the first of 15 admissions to Northampton State Hospital in 1871. Like his sister, he had "recurrent mania," but unlike his sister he was often violent, sometimes ended up in jail, and often escaped from the hospital, only to be forcibly returned. His pattern of care paralleled that of Ms. A: short hospitalizations, followed by one much longer hospitalization after the father's death, one subsequent brief trial at home with the family, and then a final readmission lasting until his death in 1917.

Much in the psychiatric histories of this sister and brother sounds quite contemporary. They each had a chronic disease with acute exacerbations in a pattern recognized by modern researchers as the life course of untreated bipolar affective disorder (35). The family is an excellent case study of the genetic basis for the disorder; in fact, the cause of insanity listed in the records of both patients was "heredity." In a scenario that seems quite contemporary, the brother objected strenuously to being held at the state hospital against his will. In 1893 his record indicated, "Thinks it a great injustice for him to be allowed no chance to try life outside [the hospital]." The patients' histories of returning home to their father's care at each discharge, but no longer being able to be cared for and needing state hospital asylum once their father was deceased, presages by a century concerns and needs expressed by families who must care for relatives with chronic mental illness (36–38). Finally, Ms. A's and her brother's pattern of high numbers of admissions to the state hospital is remarkably contemporary; equally remarkable is how unusual it was in their time. They are the only two patients to have had 10 or more admissions for at least the first half-century that Northampton State Hospital was in operation.

DISCUSSION

At no time since the Asylum at Williamsburg opened its doors in 1773 as the first public hospital for the care and treatment of the mentally ill has it been harder to be admitted to a state hospital than in the last 15 years. But it is also true that at no time prior to the last 15 years have so many patients accumulated so many admissions. We are truly in the era of the revolving door.

There have been various contemporary explanations of the recidivism phenomenon, which this historical perspective refutes somewhat. Some authors have indicated that in the nineteenth century few persons were ever discharged, and the low rates of recidivism were simply an artifact of no potential candidates for readmission. For example, Ridgway and Zippel (39) stated, "If one were admitted to such an asylum and not dis-

charged rapidly, the institution often became one's 'home'. The data presented here indicate that persons were admitted, treated over periods of weeks to years, and discharged. The notion that few persons left nineteenth-century state hospitals alive is not supported by the Northampton State Hospital data.

Weinstein (40) has indicated that current recidivism rates are partly an artifact of changed regulations and procedures concerning "visit" or "convalescent" status; i.e., patients leave the hospital but remain on the books, so that their return to the hospital is not tabulated as a readmission. While "paroling" patients was not a common nineteenth-century practice, it was not unknown to the alienist of that era (41). The use of visit status was a common practice in the 1930s. However, if we use the same criteria as were used at Northampton State Hospital in the 1980s (visit status could be granted for up to 30 days' duration) and thereby convert returns from visits of over 30 days in 1936 to readmissions, we would increase the recidivism rate from 17.6% to 24.7%, or still only about one-third the 1980s repeat admission rate.

Weinstein (40) also accounted for the apparent readmission explosion by a decrease in the rate of first admissions. This is certainly the case, as shown in table 2. Great effort has gone into creating contemporary systems to divert admissions from public facilities to private alternatives (42). This is not, however, because of some new realization of the potential benefits of such diversion. Jarvis (43), in 1860, reported quite cogently on this practice: "For those insane patients who can be managed under personal influences and in proper circumstances, there are some advantages and privileges which can be enjoyed in a higher degree in private and discreetly managed houses than in public establishments" (p. 27).

As this review indicates, it is not a change in the clinical characteristics of patients, nor a change in the etiology of mental disorders, nor a change in contemporary beliefs in innovative clinical interventions, nor a change in therapeutic optimism, nor even a change in the moral dilemmas of providing care that accounts for the current phenomenon of state hospital recidivism. Rather, the role of the state hospital has been altered by factors extrinsic to both the provider and the recipient of psychiatric services. And the state hospital, as shown, has been profoundly altered. It is hoped that understanding the history of the state hospital will help us to chart its future better. Granted, many aspects of the functioning of state hospitals in the past have been questionable at best. But does the current role of the state hospital—in which society refuses to permit asylum to those who are unable to function without its succor while simultaneously condoning a system of care whereby some individuals are admitted more than 100 times—make any sense?

Meta-Analysis of Subjective Sensitivity to Alcohol in Sons of Alcoholics

Vicki E. Pollock, Ph.D.

***Objective:** Meta-analysis was used to review the research literature on self-reported sensitivity to alcohol among sons of alcoholic and among normal control subjects. **Method:** Computerized and manual searches identified 17 eligible independent articles; nine contained the information necessary to compute effect sizes, and additional data on two other studies were provided by authors in response to written and telephone requests. **Results:** Findings from 10 studies indicated that sons of alcoholics report significantly less sensitivity to alcohol than normal control subjects overall and during the ascending (i.e., 0–35 minutes after alcohol) and descending (i.e., 40–240 minutes after alcohol) limbs of the blood alcohol curve. Response to placebo did not significantly distinguish these groups in the five studies that included such assessment. **Conclusions:** It may be appropriate to apprise the biological sons of male alcoholics that they may experience less subjective sensitivity to alcohol than other individuals, but it is not possible to predict whether any particular individual will experience such lower sensitivity. In addition, self-report data can be influenced by many factors, and further research that assesses multiple psychological and physiological measures and uses longitudinal designs is needed to determine the relationship between specific factors and the development of alcoholism.*

(Am J Psychiatry 1992; 149:1534–1538)

Sons of alcoholics are a group at high risk for developing alcoholism. In the past decade, multiple research studies have compared self-reported sensitivity to alcohol effects among sons of alcoholics and normal control subjects. Two differing theoretical perspectives have emerged from this research.

One theoretical perspective is that sensitivity to alcohol effects in sons of alcoholics varies depending on the blood alcohol curve (1). Under this view, sons of alcoholics exhibit greater than normal sensitivity to alcohol during the ascending limb, when its positive effects are purportedly greatest, and lower than normal sensitivity to it during the descending limb, when alcohol's negative effects are reportedly dominant. Thus, sons of alcoholics are vulnerable to developing alcoholism because the greater subjective sensitivity they possess during the ascending limb reinforces their drinking, and this is coupled with their relative imperviousness to alcohol's negative effects.

A second theoretical perspective is based on the premise that sons of alcoholics possess less subjective sensitivity to alcohol than do normal individuals (2). According to this view, sons of alcoholics are more vulnerable to developing alcoholism because they are less sensitive to alcohol effects after three to five drinks than are control subjects. Hence, they find it more difficult to regulate their alcohol consumption because they receive less internal feedback at these lower doses. Consequently, because they lack sensitivity to cues that normal subjects use to regulate drinking, sons of alcoholics are likely to consume more alcohol than do normal individuals within drinking sessions, and over time this contributes to the development of dependence.

In this study meta-analysis was used to review the empirical research literature on the self-reported sensitivity to alcohol of sons of alcoholics and of control subjects. Meta-analysis embodies a variety of techniques that quantitatively summarize the results of a number of individual studies designed to address a common theme or issue (3–5). Individual study outcomes in meta-analysis are usually represented by an effect size. Unlike statistical significance testing, in which the likelihood of group differences is inferred by using a binary decision strategy, the effect size provides an index of the magnitude of difference that distinguishes groups. Typically, the effect sizes culled from individual studies constitute the dependent variables examined in meta-analysis.

Received July 23, 1991; revision received March 10, 1992; accepted April 10, 1992. From the Department of Psychiatry and Behavioral Sciences, University of Southern California School of Medicine. Not all sons of alcoholics are likely to develop alcoholism themselves. The effect size and hence the statistical power based on comparisons of sons of alcoholics and normal control subjects are therefore likely to be less than those in studies in which pre-alcoholics are compared with normal subjects. Because low statistical power may account for the apparent divergence in some of the results reported to date, the aggregation of effect sizes by meta-analysis might prove especially helpful in assessing the overall consistency of findings in this research literature (e.g., 6).

In this report meta-analysis is used to evaluate hypotheses derived from each of the two theoretical perspectives already described. According to the first theoretical perspective, sons of alcoholics will report greater sensitivity to alcohol effects during the ascending limb of the blood alcohol curve than will normal control subjects but less sensitivity to it during the descending limb. According to the second theoretical perspective, sons of alcoholics will report less sensitivity to alcohol after alcohol ingestion than will control subjects.

METHOD

Identification of Studies

Two computerized literature searches, one on MEDLINE for 1985 through February 1991 and one on PsycINFO for 1984 through February 1991, were used to supplement the pool of published studies identified in prior reviews (1, 7). Manual searches of the reference sections of each review and individual study were performed to identify additional articles. Informal questioning of researchers in the area was used to locate relevant unpublished work.

Nineteen articles were identified. One (8) was eliminated because it evaluated women exclusively, and this meta-analysis assessed men. A second article (9) was excluded because the subject group consisted of a mixture of identical and fraternal twins and sibling pairs, and in this case it was not clear how to compute an effect size that could be meaningfully compared to those of the other studies. Thus, the total number of studies potentially available for the present meta-analysis was 17 (10–26).

In nine studies the information necessary to compute the effect sizes for between-group designs was available in the text or tables (13, 19–22, 25) or graphs (18, 23, 24). Letters requesting additional data were sent to the authors of some of these studies, and two responses were received. Specifically, Moss et al. (18) provided complete numeric data, so it was not necessary to estimate these values from the graphs. Vogel-Sprott and Chipperfield (25) provided data on four time points (30, 70, 80, and 130 minutes postalcohol), and this information was used in addition to the data for the 60-minute time point that were published in their article.

The eight remaining studies did not contain enough information to compute the effect sizes. Additional in-

formation was requested through a letter or telephone call to the primary author or the author identified as the correspondent in the published article (10–12, 14–17, 26). Of the responses received, two contributed data to this meta-analysis (10, 12).

In total, 11 independent research studies provided data for the present meta-analysis. The methods for assessing the subjects' self-ratings varied in these studies. In seven of them, the subjects' self-ratings of how "high" or "intoxicated" they were constituted the dependent variable selected for this meta-analysis (10, 12, 18, 20, 21, 23, 25). In two studies, the dependent variable was the subjects' self-ratings of how much the alcohol (19) or the drug (24) had affected them. In the two remaining studies, the total score on the Sensation Scale (13) or the score on the central stimulant subscale of the Sensation Scale (22) was used.

Effect Sizes

The effect size for each study was computed as the mean for the control group minus the mean for the group of sons of alcoholics divided by their pooled standard deviation (4, p. 78). Although some studies obtained self-ratings at baseline (i.e., before beverage administrations), frequently none of the subjects reported feeling affected by alcohol at this time point. Therefore, this time point was discarded from all analyses because virtually no effect sizes for it could be computed. For the remaining data, the number of effect sizes computed per study ranged from one (13) to 24 (three doses multiplied by eight time periods) (18).

Subgroups of subjects were examined in two studies. In both of them, effect sizes were computed as averages over subgroups, weighted by group size, so that all of the subjects' data examined in the original studies were represented. The rationale underlying this decision was to avoid biasing the meta-analysis results by failing to include all subjects. Thus, in one study in which the sons of alcoholics consisted of two subgroups—those with trans- versus unigenerational family histories of alcoholism (13)—the effect size computed was based on the weighted average of the two subgroups contrasted with the control subjects. In the other study, the four subgroups examined were sons of alcoholic and control subjects with and without antisocial personality disorder (10). These effect sizes were constructed by using a weighted average to compare subjects with and without family histories of alcoholism irrespective of antisocial personality disorder.

Plan of Analyses

Separate analyses were used to assess group differences under the alcohol and placebo conditions. All meta-analyses were based on studies weighted according to their group sizes (4).

First, an overall meta-analysis was used to assess differences between the self-reported sensitivity to alcohol of sons of alcoholics and that of control subjects. For

^aEffect size.

this comparison, one effect size per study was computed by averaging the effect sizes within single studies across time periods and alcohol doses. In addition, in a second set, separate analyses of two time periods following alcohol administration (time period 1: 0 to 35 minutes; time period 2: 40–240 minutes) were performed. Within each of these two time periods, multiple effect sizes per study were typically available. Again, the effect sizes used to represent the studies within each time period were obtained by averaging them across the relevant time periods and alcohol doses within studies. Once derived, the correction for bias described by Hedges and Olkin (4, p. 81) was applied to each effect size.

In some studies the control subjects did not differ in sex or age from the sons of alcoholics, whereas in others these groups were explicitly matched for sex and age, as well as other variables. The computation of effect sizes for within-group designs differs from that for between-group designs (27, p. 48), but none of the studies reported the information necessary to compute effect sizes for the former. Therefore, in the present study all effect sizes were computed by assuming between-group designs. The bias induced by this decision is likely to lead to underestimation of group differences (27) if, in fact, the within-group design reduces variance that is extraneous to the group comparisons.

The meta-analysis of the placebo sessions included the results reported in all relevant studies except for one in which reliable estimates of the effect size could not be obtained from the graph (24). A single effect size was used to represent each study in this meta-analysis. As already described, if data were acquired at multiple time periods, the effect sizes were averaged before the correction for bias was applied (4, p. 81).

RESULTS

Alcohol Sessions

Ten studies yielded information on the response to alcohol of 192 sons of alcoholics and 182 control subjects (table 1). The overall mean effect size of 0.34 is small to moderate (27). Its direction indicates that sons of alcoholics report less sensitivity to alcohol than do control subjects. The group difference is statistically significant in that the two-sided 95% confidence interval surrounding it excludes zero (i.e., 0.13 to 0.55).

To assess the hypotheses that sons of alcoholics exhibit greater than normal sensitivity to alcohol during the ascending limb but less sensitivity during the descending limb of the blood alcohol curve, separate mean effect sizes and confidence intervals were derived for the seven studies that obtained subjects' self-ratings 0 to 35 minutes after alcohol administration and for the 10 studies that obtained these data 40 to 240 minutes after alcohol. The results indicate that sons of alcoholics report significantly less sensitivity to alcohol than do normal subjects during both time periods: for 0–35 minutes the mean effect size was 0.32 and the two-sided 95% confidence interval was 0.07 to 0.56 (sons of alcoholics, $N=140$; control subjects, $N=140$), and for 40 to 240 minutes the mean effect size was 0.33 and the two-sided 95% confidence interval was 0.12 to 0.54 (sons of alcoholics, $N=184$; control subjects, $N=174$).

Placebo Sessions

Five studies yielded information on the response to placebo of 76 sons of alcoholics and 125 control subjects (table 1). The overall mean effect size of 0.08 is small.

Because its 95% confidence interval includes zero (i.e., -0.22 to 0.38), these results indicate that self-reported sensitivity to placebo does not significantly distinguish sons of alcoholics from control subjects.

DISCUSSION

The meta-analysis results indicate that sons of alcoholics report significantly less sensitivity to alcohol after alcohol ingestion than do normal control subjects. The sons of alcoholics' self-ratings of alcohol effects were significantly lower than those of control subjects during the ascending (i.e., 0–35 minutes after alcohol administration) and descending (i.e., 40 to 240 minutes after alcohol administration) limbs of the blood alcohol curve. The self-ratings obtained after placebo administration did not significantly distinguish sons of alcoholics from normal control subjects.

The meta-analysis findings clearly support the theoretical perspective that sons of alcoholics report less sensitivity to alcohol than do normal control subjects (2). These results provide no support and, in fact, contradict a hypothesis derived from an alternative theoretical view, which specifies that sons of alcoholics exhibit greater sensitivity to alcohol than control subjects during the ascending limb of the blood alcohol curve (1).

Multiple methodological moderators, such as the nature of the subject groups, between- versus within-group designs, differences in the methods of assessing subjective sensitivity, variations in the alcohol doses administered to subjects, and the time periods at which self-ratings were acquired, were not examined in this work. The influence of such factors can be evaluated by meta-analysis (3–5). However, because the present review was based on a small set of studies, it seems unlikely that meta-analytic evaluation of these methodological factors would yield stable results (28). Therefore, no such moderator analyses were undertaken.

Approximately two-thirds of all of the eligible studies identified (i.e., 11 of 17) contributed data to the meta-analysis. The possibility of bias in the meta-analysis results reported here due to the exclusion of six studies cannot be definitively discounted. Nonetheless, I attempted to obtain data for all studies and I have no reason to believe the 11 studies that provided the data are an unrepresentative subset.

Response to placebo failed to distinguish the sons of alcoholics from control subjects. This result, however, requires cautious interpretation because more studies obtained data in alcohol than in placebo conditions (i.e., 10 versus five, respectively). Consequently, the statistical power for detecting effects may have been greater for the alcohol condition. Within single empirical studies, placebo sessions are critical for assessing factors that might be important in understanding subjective responses to alcohol or other substances. Thus, the fact that the present meta-analysis failed to reveal a significant difference between the sons of alcoholics and control subjects in their responses to placebo

should not be used as a rationale to omit or discontinue placebo sessions in individual empirical research studies. Indeed, because of possible bias arising from subject and experimenter expectancy effects, results of placebo sessions are critical for interpretation of individual study results.

The mean effect size obtained in this meta-analysis can be used in conjunction with the specification of other design features to estimate the number of subjects that would be necessary to document statistically significant differences between sons of alcoholics and control groups in this type of research most of the time (i.e., power=0.80). By using a between-group design, a bidirectional significance test, and a type I error of 0.05 (i.e., $\alpha=0.05$), most of the time (i.e., power=0.80) comparisons of approximately 137 sons of alcoholics and 137 control subjects would be needed to demonstrate that sons of alcoholics exhibit less sensitivity to alcohol. These sample size estimates could, however, be lessened substantially if the error variance were reduced, as can sometimes be achieved by using a within-group design. If, for example, a within-group design in which the correlation between the matched groups' scores of 0.85 was used in conjunction with the design features already specified (i.e., power=0.80, bidirectional significance test with type I error of 0.05), then approximately 21 sons of alcoholics and 21 control subjects would provide a sample size sufficient to demonstrate these same group differences.

The results of this meta-analysis are consistent with the suggestion that it might be appropriate to apprise the biological sons of male alcoholics of the possibility that they may experience less subjective sensitivity to alcohol than other individuals. Specifically, these offspring could be informed that after consuming low to moderate doses of alcohol they might feel as though they are not as affected (or as "high" or intoxicated) as other individuals (see, for example, reference 24). Also, it might be appropriate to describe one possible way in which this risk factor could influence the development of alcoholism. That is, it could be explained that sons of alcoholics who report less subjective sensitivity to alcohol might be more likely to consume more alcohol than other individuals and that this might contribute to excessive alcohol use that leads to abuse or dependence. In addition to imparting such information, it should be emphasized that the limitations inherent in the present research studies make it impossible to predict whether any single individual will experience less sensitivity to alcohol or to specify who will develop alcoholism in the future.

The interpretation of the finding that sons of alcoholics report less sensitivity to alcohol than control subjects is not straightforward because self-report data can be influenced by many factors. For example, it is possible that the groups possess differential cognitive abilities which affect their proficiency in verbal communication or that group-related personality features mediated these findings (see reference 29 for review). Alternatively, the lower subjective sensitivity reported by sons

of alcoholics after consuming alcohol might reflect a genuine biologically mediated characteristic that distinguishes them from control subjects. This latter interpretation is supported by physiological data which suggest that sons of alcoholics manifest less intense responses to alcohol than do control subjects in terms of prolactin (30), cortisol (31), and P3 (32). Future research that incorporates multiple psychological and physiological measures is needed to assess these possibilities, even if the results are difficult to interpret because the results of studies based on multiple measures may not allow simple or straightforward interpretations.

Ultimately, the predictive validity of low subjective sensitivity to alcohol as a risk factor contributing to the development of alcoholism requires data from follow-up studies using longitudinal designs. Early results from a 10-year follow-up of sons of alcoholics and control subjects corroborate a relationship between a lower than normal reaction to alcohol and the future development of alcoholism (33). Thus, these preliminary findings attest to the etiological importance of subjective sensitivity to alcohol as a risk factor.

Cross-Cultural Differences in Rating Hyperactive-Disruptive Behaviors in Children

Eberhard M. Mann, M.D., Yoshiko Ikeda, M.D., Charles W. Mueller, Ph.D.,

Bao Ling Li, M.D., and Dorothy Chin, M.A.

***Objective:** To determine the extent to which the reported variations across countries in the prevalence of attention-deficit hyperactivity disorder are due to cultural differences among raters, the authors examined the degree to which mental health professionals in four countries differed in their ratings of hyperactive-disruptive behaviors in children. **Method:** Mental health professionals from China (N=8), Indonesia (N=12), Japan (N=9), and the United States (N=8) rated the presence and degree of hyperactive-disruptive behaviors in standardized videotape vignettes of four 8-year-old boys participating in individual and group activities. **Results:** Chinese and Indonesian clinicians gave significantly higher scores for hyperactive-disruptive behaviors than did their Japanese and American colleagues. **Conclusions:** These findings suggest that perceptions of hyperactivity vary significantly across countries even if uniform rating criteria are applied. Without correction for these perceptual differences, cross-cultural prevalence rates of hyperactivity may not be comparable.*

(Am J Psychiatry 1992; 149:1539-1542)

Wide variations across countries in the prevalence of attention-deficit hyperactivity disorder have been reported. In the United States 1%-12% of elementary school children are reportedly affected (1, 2). Surveys in England indicated a prevalence of less than 1% (3). To our knowledge, no hyperactivity was diagnosed in China before 1978 (unpublished 1977 paper by R.L. Sprague et al.), but since popularization of the concept, prevalence rates ranging from 2% to 13% have been published (4).

Most international prevalence data cannot be compared because diverse diagnostic criteria and assessment tools have been used. Application of comparable behavioral rating scales has partially reduced prevalence discrepancies in such countries as Australia, Germany, Great Britain, New Zealand, and the United States (5). However, the ways in which clinicians from

different countries use these rating systems continue to differ. For example, Prendergast et al. (6) reported that rigorous training in diagnostic categories improved but did not eliminate differences between U.S. and British research teams in assessing written case records and, in some instances, videotaped interviews for disruptive behavior disorders. Practicing clinicians in both countries showed significantly less concordance than researchers in their evaluations.

Such differences in clinicians' perceptions are likely to be even greater in comparisons of raters from countries with less similar cultural and historical backgrounds.

Because inattention, impulsivity, motor restlessness, and disruptiveness are found in all children to some degree, the diagnosis of attention-deficit hyperactivity disorder and other disruptive behavior disorders is based more on an assessment of developmentally inappropriate intensity, frequency, and/or duration of the behavior rather than its mere presence. Such judgments increase the possibility of observer bias. In particular, different culturally determined standards for normal behaviors may influence ratings of observed behaviors. Especially in nonpsychotic psychiatric illness, cultural background has been demonstrated to have a substantial influence on the interpretation of behavior as normal or pathological (7). This suggests that prevalence studies for any disorder should not be undertaken in the absence of prior knowledge about cross-cultural differences in the interpretation of the behaviors of interest.

^eAdded by research team.

In planning for a standardized, cross-cultural prevalence survey of attention-deficit hyperactivity disorder in China, Indonesia, Japan, and the United States, we examined if and to what degree mental health professionals in the targeted countries differed in their ratings of hyperactive-disruptive behaviors.

METHOD

Videotape vignettes of four 8-year-old boys, two from Honolulu and two from Tokyo, were prepared under standardized conditions. The two boys at each site were selected from an outpatient clinic pool and a neighborhood elementary school, respectively. Since the purpose of the study was to examine the extent of rater differences in assessing observed behaviors, a diagnostic evaluation of the children was not required. However, children with marked physical handicaps, mental retardation, pervasive developmental deviations, or psychotic disorders were excluded. Each child was filmed alone and in a group. For the individual activity, the child was asked to sit at a table and draw a picture. He was told that he could play with any of the toys displayed in the video room as soon as he had completed his drawing. In the group activity, the child and two to three other male age mates were asked to build a block tower together. The children were told that they could play with any of the toys in the room after the tower fell over or was completed.

For each child, the videotapes were edited into an 8-10-minute segment with equal time for the individual and group activities. Through this editing, various degrees of targeted behaviors were emphasized, but extremes such as pervasive withdrawal or excessive aggressiveness were deleted.

An 18-item behavior observation checklist was developed (figure 1). Each item described a behavior that could be observed on the videotape without additional information about the child. All items except item 18 were directly derived from the *DSM-III-R* symptom checklist for disruptive behavior disorders (attention-deficit hyperactivity disorder, oppositional defiant disorder, conduct disorder) or the Abbreviated Conners Teacher's Rating Scale for hyperactivity (8).

Items from *DSM-III-R* and the Abbreviated Conners Teacher's Rating Scale were chosen because of the popular use of these instruments for rating and diagnosing disruptive behavior disorders in research. These rating systems have demonstrated positive psychometric qualities, including sensitivity, specificity, internal consistency (9), test-retest reliability (8), and convergent validity (10). Item 18 was added by the research team to specify physically aggressive acts.

Items 1-12 were to be rated for the child's solitary activity, and items 1-18 were rated for the group activity. Each item was rated on a 4-point scale ranging from 0 ("not at all") to 3 ("very much"). Therefore, the maximum attainable scores for individual and group

activities were 36 and 54, respectively. The behavior observation checklist was translated into Chinese, Indonesian, and Japanese and checked for accuracy through back-translation.

All of the raters were mental health professionals with experience in treating children. In China eight raters participated. Three were trained child psychiatrists, three were child psychiatry residents, and two were social workers. All but one had worked with children diagnosed as hyperactive. In Hawaii eight raters participated: four child psychiatrists, three child psychiatry residents, and one social worker. All had worked with children diagnosed as hyperactive. In Indonesia 12 raters participated: five child psychiatrists, five child psychiatry residents, one general psychiatry resident, and one psychologist. All but one had worked with children who were considered hyperactive. In Japan nine raters participated: two child psychiatrists, three general psychiatrists, three psychologists, and one social worker. All but two had worked with children diagnosed as hyperactive.

The videotapes were presented in the same order to all raters, who completed the behavior observation checklist immediately after each child's individual or group activity was shown.

Interrater reliability was assessed separately for the individual and group activity ratings. Overall mean scores for individual activity and group activity were analyzed by using separate split-plot analyses of variance.

RESULTS

Reliability Estimates

Intraclass correlation coefficients were calculated separately for the individual activity ratings and group activity ratings within the raters of each country (11). As shown in table 1, seven of the eight intraclass correlation coefficients were positive and substantial, indicating in these seven cases a satisfactory level of agreement among raters within any given country. The one negative value was strongly influenced by the great variation among the Chinese raters' group activity scores and relatively little variation across tapes.

Two more intraclass correlations were calculated to examine variation among the different countries for the individual and group activities. The intraclass correlation coefficients were 0.86 for the individual activity and 0.86 for the group activity, indicating that a high level of variance was accounted for by the rater's country of residence.

Between-Country Comparisons

Individual activity. A 4×4 (rater's country of residence and videotape) split-plot analysis of variance of the scores for the individual activity indicated significant main effects for rater's country of residence ($F=18.30$, $df=3, 32$, $p<0.001$) and for videotape ($F=19.40$,

Japan	0.47	11.7 _z	7.3

^aThe numbers of raters were as follows: China, N=8; Indonesia, N=12; United States, N=8; Japan, N=9.

^bStatistical logic and calculation procedures according to Bartko and Carpenter (11).

^cMeans with different subscripts are significantly different ($p<0.05$, Scheffé test).

$df=3, 96$, $p<0.001$). The interaction between rater's country and tape was nonsignificant ($F=1.01$, $df=9, 96$, $p>0.40$).

As shown in table 1, the mental health professionals from China and Indonesia made significantly higher ratings than the professionals from Japan and the United States ($p<0.05$ in all cases, according to the Scheffé test).

Tests of the main effect for videotape indicated that one tape significantly differed from the other three ($p<0.05$, Scheffé test). These differences, along with the absence of any interaction between rater and tape, confirm that a relatively broad range of disruptive behaviors were depicted in the videotapes and that the effects related to rater's country of residence were independent of these videotape characteristics. In fact, the pattern depicted in table 1 held for all four videotapes independently, further attesting to the generality of these statistical differences.

Group activity. A 4×4 (rater's country of residence and videotape) split-plot analysis of variance was also conducted on the scores for the group activity. Again, the results indicated main effects for rater's country of residence ($F=8.61$, $df=3, 32$, $p<0.001$) and for videotape ($F=10.36$, $df=3, 96$, $p<0.001$), whereas the interaction was nonsignificant ($F=0.85$, $df=9, 96$, $p>0.50$).

Further examination of the main effect for rater's country of residence by using Scheffé tests demonstrated that the mental health professionals from China made significantly higher ratings than did the professionals from Indonesia, who in turn gave higher ratings than American or Japanese raters (all $p<0.05$) (table 1).

As with the individual activity scores, the main effect for videotape on the group activity scores indicated a wide range of symptom levels. Again, country of residence had a clear and independent effect across all videotapes.

DISCUSSION

The results from the present study show substantive and reliable differences in ratings of hyperactive-disruptive behaviors in children among mental health professionals from four different countries. Specifically, clinicians from China and Indonesia rated target behaviors for all children higher than did clinicians from the United States and Japan. Since all raters observed identical tapes, the disparities are more likely due to differences in perception than to any differences in actual symptom level. This may reflect different cultural standards for appropriate childhood behaviors. For example, in China emotional control and conformity are valued and expected from preschool on, permissiveness and student self-regulation with little direct teacher discipline is characteristic for the lower school grades in Japan, and individual expression and creativity are emphasized in the United States (12).

Significant differences in cultural perceptions of symptoms may complicate comparisons of epidemiological studies of disruptive behavior disorders in different countries, especially if rating scales and behavioral observation are used as primary diagnostic tools. For example, even though the prevalence rates of attention-deficit hyperactivity disorder in China are reportedly similar to those in the United States (13), it remains unclear whether boys considered hyperactive in China would be diagnosed as hyperactive in the United States or Japan.

Any cross-cultural epidemiological study of disruptive behavior disorders, particularly attention-deficit hyperactivity disorder, which is diagnosed in terms of dimensional rather than categorical symptoms, will need to address the issue of perceptual differences in symptom interpretation.

While this study demonstrated significant cross-cultural variations in the perception of disruptive childhood behaviors, it did not assess whether higher scores were related to determining pathology and need for treatment. Such research should be done. Future research also should compare ratings of parents and other professionals—such as teachers and pediatricians, who frequently assess children's behaviors—in different countries. Specific symptoms should be analyzed to distinguish between those which seem to be universally perceived and those which are more culturally dependent. By building this data base, future epidemiological research will become more interpretable.

Finally, combining approaches that examine the meaning of the disruptive child within each culture with approaches that train mental health diagnosticians in different countries to effectively use universal, standardized criteria may be a useful method for achieving greater comparability of data (11, 14). The formation of cross-cultural diagnostic research teams might aid in this process.

Deterioration in Premorbid Functioning in Schizophrenia: A Developmental Model of Negative Symptoms in Drug-Free Patients

Mary E. Kelley, B.S., Mark Gilbertson, Ph.D.,
Andrew Mouton, Ph.D., and Daniel P. van Kammen, M.D., Ph.D.

Objective: The authors examined the relationship between negative symptoms and premorbid variables in drug-free schizophrenic patients. **Method:** The authors studied 63 clinically stable male schizophrenic inpatients who were not receiving any psychoactive medication. The patients were classified as having negative, positive, or mixed symptoms, and their premorbid functioning during childhood, early adolescence, and late adolescence was assessed by using the Premorbid Adjustment Scale. Correlational analyses were applied to the classification and developmental models. **Results:** Patients with negative symptoms had significantly lower levels of premorbid functioning during late adolescence and significantly greater premorbid deterioration between childhood and early adolescence. Correlational analysis revealed significant positive relationships between premorbid variables and negative symptoms. **Conclusions:** The data suggest that a deterioration in social and intellectual functioning between childhood and adolescence is associated with the development of a negative symptom syndrome in schizophrenia. The premorbid deterioration appears to be an early prodrome of the disorder. Whether this residual negative symptom syndrome is in some way related to the deficit syndrome of schizophrenia awaits a prospective study.
(Am J Psychiatry 1992; 149:1543-1548)

In the study of schizophrenia, much emphasis has been placed on subtyping in order to predict outcome and response to neuroleptic treatment. In 1980, Crow proposed the negative symptom syndrome of schizophrenia (1). Negative symptoms were thought to be nonresponsive to medications (2) and persistent over time (3, 4), suggesting a chronic condition. However, some negative symptoms have been shown to be state dependent in that they are drug responsive (4-7), increase with psychotic relapse (8, 9), and increase with drug withdrawal (10). In addition, negative symptoms have been found to respond to amphetamine administration (11). There is also an indication that negative symptoms can be the result of understimulation in the patient's social environment and are therefore reduced by behavioral intervention (12).

Some of these apparently conflicting findings may be

the result of an unclear definition of negative symptoms. Although some investigators proposed that poor social functioning and attentional impairment may be considered negative symptoms (13), Crow (14) suggested limiting the definition to flattening of affect and poverty of speech only. The specificity of negative symptoms to schizophrenia has also been questioned (15).

Carpenter et al. (16) attempted to solve this issue by making a distinction between deficit and nondeficit syndromes. In this paradigm the severity and persistence of symptoms are more important than the definition of symptoms; consistent negative symptoms that are not caused by depression, anxiety, medication effects, or environmental deprivation must be present for a period of at least 1 year. Symptoms are considered consistent if they show no response to neuroleptic treatment and do not lessen with remission of psychotic symptoms (16).

Explorations of negative symptoms led to the investigation of their relationship to poor premorbid social adjustment, which had been found to be correlated with several other negative variables such as poor outcome (17), poor drug response (18, 19), and CT scan abnormalities (20). Andreasen and Olsen (21) used a classification model (groups with positive, negative, and mixed symptoms) and showed that premorbid adjustment measured by the Phillips Scale (22) was significantly poorer in the group with negative symptoms.

Received Sept. 10, 1991; revision received Feb. 12, 1992; accepted Feb. 27, 1992. Funded by a VA Merit Review grant (Dr. van Kammen).

The authors thank the subjects; Doris McAdam, Head Nurse; and the staff of the Schizophrenia Research Unit, Highland Drive DVAMC, for their dedication and assistance. They would also like to acknowledge the suggestions of the late Dr. Joseph Zubin.

Andreasen et al. (23) replicated this finding in a more recent sample. Pogue-Geile and Harrow (3) reported a significant relationship between a fair or poor rating (lack of close friends, small number of acquaintances) of premorbid functioning and a negative symptom score. Davis and DeWolfe (24) reported a significant relationship between poor premorbid scores on the Phillips Scale and flattened affect measured by high scores on the MMPI psychasthenia scale (signifying inhibition of physical activity). Buchanan et al. (25) showed that poor premorbid functioning was also a component of the deficit syndrome (16). Not all studies have observed this relationship, however (2).

The Premorbid Adjustment Scale (26), introduced by Cannon-Spoor et al. in 1982, separated premorbid functioning into distinct life periods (childhood, early adolescence, late adolescence, and adulthood), which allows for an analysis of the developmental aspects of premorbid functioning. In their original assessment of schizophrenic patients (26), Cannon-Spoor et al. found a progressive deterioration in functioning through childhood, early adolescence, and late adolescence, with mean scores of 0.35, 0.44, and 0.52, respectively. This apparent deterioration in functioning suggested that negative symptoms could be studied in relation to a premorbid developmental model. Furthermore, the Premorbid Adjustment Scale rates both social and intellectual functioning; therefore, different aspects of premorbid functioning can be examined separately (27). Buchanan et al. (25) used this scale in their evaluation of aspects of the deficit syndrome.

Recently, Mukherjee et al. (27) proposed a premorbid developmental model for negative symptoms based on the Premorbid Adjustment Scale. Mukherjee et al. found evidence that the deterioration of functioning between childhood and early adolescence correlated with ratings of negative symptoms. Their study as well as many previous studies evaluated patients who were receiving medication. However, because negative symptoms can be drug responsive as well as drug induced (7, 11, 28), an evaluation of negative symptoms in drug-free subjects, without the complication of a psychotic exacerbation, may be a paradigm of residual negative symptoms that can be used to test this developmental hypothesis. In addition, evaluation of drug-free subjects is preferred due to the fact that patients with poor premorbid functioning may be given higher doses due to treatment resistance (18, 29), thus creating a systematic bias.

In the present study, we used negative symptom data from drug-free patients involved in our double-blind haloperidol withdrawal study (8). The data were analyzed by using correlational analyses as well as a modification of the classification approach of Andreasen et al. (23) to study the relationship between a premorbid decrease in adaptive functioning and the presence of negative symptoms in drug-free schizophrenic patients. The correlational analyses were used to address the issue of whether a negative syndrome is better studied as a category or as a continuous dimension (30).

METHOD

Subjects

The subjects were 63 male veterans admitted to our schizophrenia research unit. All of these patients had a *DSM-III-R* diagnosis of schizophrenia ($N=55$) or schizoaffective disorder ($N=8$). Information for the diagnosis was obtained by using the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (31) as well as past medical records and contacts with the patient's family if possible. All diagnostic information was reviewed in a multidisciplinary case conference, and a consensus diagnosis was obtained. Fifty-three of the patients participated in a double-blind protocol that consisted of the replacement of long-term antipsychotic drug treatment with a stabilization period of haloperidol administration. If the patient had received a decanoate injection, he was not considered stable unless he had taken only oral haloperidol for at least 3 months. After the stabilization period, the unmarked haloperidol capsules were replaced by placebo capsules for up to 6 weeks. Another 10 clinically stable patients received a double-blind placebo trial on admission; these patients showed no recent psychotic exacerbation, although they may have been symptomatic at the time.

The mean age at the time of study of the 63 patients was 34.9 years ($SD=8.3$). Their mean age at first onset of psychotic symptoms was 22.9 years ($SD=4.8$). They had been ill with schizophrenia for a mean of 12.0 years ($SD=7.3$). Their mean number of years of formal education was 12.0 ($SD=1.8$).

Measures

Premorbid functioning was assessed by using the Premorbid Adjustment Scale (26); the scores were based on extensive information from the patient, the patient's family, and previous records. Data on the late adolescent period were not available for two patients because they developed schizophrenia before reaching this age period. Change scores were computed by subtracting the patients' childhood scores from their early adolescence scores (27). Because of the noticeable effect of the features of their illness on the adult premorbid scores, only the first three life periods were used for this analysis.

Although data for this scale have ordinarily been presented as percentages, reporting means gives the benefit of being able to refer to the 7-point scale measurement (0–6=normal–severely impaired) to assess the relationships between groups. (Percentage scores comparable to those in the previous literature can be computed by dividing the values presented by 6, the highest possible score.)

The Scale for the Assessment of Negative Symptoms (13) and the withdrawal cluster of the Brief Psychiatric Rating Scale (BPRS) (32) were used to assess negative symptoms. Positive symptoms were assessed for classification purposes by using the BPRS psychosis items

TABLE 1. Demographic and Clinical Characteristics of 63 Drug-Free Male Schizophrenic Inpatients With Positive, Mixed, or Negative Symptoms

Characteristic	Positive Symptoms (N=23)		Mixed Symptoms (N=28)		Negative Symptoms (N=12)		Analysis of Variance

that most closely corresponded to the positive criteria of Andreasen et al. (23)—1) hallucinatory behavior, 2) suspiciousness (i.e., delusional behavior), 3) conceptual disorganization/disorganized speech, and 4) unusual thought content and grandiosity. Because the strict application of Andreasen's negative symptom criteria resulted in classifying only three patients as having negative symptoms, we increased the sensitivity of the classification to our sample by extending the criterion to include a score of 3, indicating moderate negative symptoms. The final classification resulted in 12 patients with negative symptoms, 23 with positive symptoms, and 28 with mixed symptoms. None of the patients in the group with negative symptoms had a schizoaffective diagnosis.

Negative symptom ratings were done weekly by therapists blind to medication status; the ratings used for this study were taken after at least 2 weeks into the drug-free period in an attempt to eliminate the effects of drug withdrawal on the ratings. To avoid the confound of a psychotic relapse during the 2–6-week drug-free period, negative symptom ratings made when the patient's psychosis score was less than 2 points higher than his baseline psychosis score (determined while he was receiving haloperidol) were chosen. The psychosis score was determined on a 15-point global rating scale (33).

To maintain interrater reliability, interview sessions were held weekly; after the rating session, the therapists examined the discrepancies and discussed them. The data from these sessions were compiled every 6 months, and intraclass correlation coefficients were computed for all the items.

Statistics

For the first analysis, multivariate analysis of variance (ANOVA) was used to assess group differences in all premorbid adjustment variables (childhood, early adolescence, and late adolescence). Similarly, univariate ANOVA was used to assess the differences in demographic and premorbid deterioration variables across groups.

For the second analysis, Pearson correlational analyses were performed on the premorbid adjustment items and negative symptoms as well as a resultant negative factor score obtained from principal components analysis.

RESULTS

No differences in age at the time of the study, age at first onset of psychotic symptoms, duration of illness, or number of years of formal education were found among the patients with negative, positive, and mixed symptoms (table 1). Fifty-nine patients remained drug free for a mean of 33.0 days (SD=13.6); four patients never received drugs.

First Analysis

An ANOVA on the premorbid deterioration variable (early adolescence Premorbid Adjustment Scale score minus childhood score) indicated that the change in overall functioning between childhood and early adolescence was significantly different among groups and that the subjects with negative symptoms exhibited the most deterioration (table 1).

Because the univariate tests indicated a distinct pattern of deterioration, multivariate ANOVA using the three life periods as dependent variables was performed to test the hypothesis that the combination of these variables may provide additional support for the developmental model. This analysis did not reveal a significant main effect for Group (Hotelling's $T=0.194$, $F=1.78$, $p=0.11$).

Second Analysis

The results of Pearson correlation analyses are presented in table 2. It is interesting to note that avolition-apathy, anhedonia-asociality, and emotional withdrawal did not correlate with premorbid adjustment items. The same pattern of deterioration noted in the classification analysis was observed.

TABLE 2. Correlations Between Premorbid Functioning and Negative Symptoms in 63 Drug-Free Male Schizophrenic Inpatients With Positive, Mixed, or Negative Symptoms

Test of Schizophrenic Symptoms	Correlation With Score on Premorbid Adjustment Scale							
	Childhood		Early Adolescence		Late Adolescence ^a		Premorbid Deterioration ^b

Blunted affect	0.20	n.s.	0.31	0.01	0.34	0.007	0.22	n.s.

^aData are missing for two patients because their onset of schizophrenia occurred before late adolescence.

^bEarly adolescence score on the Premorbid Adjustment Scale minus childhood score on the Premorbid Adjustment Scale.

^cn.s.= $p > 0.10$.

Because the number of correlations inhibited the interpretation of these findings, we performed a data reduction using principal components analysis (varimax rotation), which resulted in a single factor score with the following component loadings: affective flattening, 0.852; blunted affect, 0.789; alogia, 0.785; emotional withdrawal, 0.769; anhedonia-asociality, 0.748; avolition-apathy, 0.717; motor retardation, 0.700; and attentional impairment, 0.611. The single factor explained 56.1% of the total variance. The correlation with this factor in childhood was $r=0.16$ ($N=63$, n.s.); in early adolescence, $r=0.33$ ($N=63$, $p=0.008$); in late adolescence, $r=0.35$ ($N=61$, $p=0.005$). (Data were missing for two patients in late adolescence because onset of schizophrenia occurred before late adolescence.) The correlation with premorbid deterioration was $r=0.30$ ($N=63$, $p=0.02$). The data reduction was successful in replicating and improving the relationships.

Additional Analyses

Although the patients were rated when clinically stable, the relationships between premorbid variables and other items of the BPRS were explored to ensure the specificity of the relationship between premorbid variables and negative symptoms. No significant relationships were found between premorbid variables and positive symptoms or depression (all p values were greater than 0.50). In addition, the analyses were performed without the eight patients with schizoaffective disorder to determine if including these patients significantly altered the relationships; no differences in the results were noted.

DISCUSSION

Our data indicate that the associations between premorbid functioning and negative symptoms found in

the previous literature (3, 25) remain significant when the effects of medication, relapse, and medication withdrawal are removed. Similarly, because we evaluated medication-free patients following withdrawal from chronic neuroleptic treatment, we found support for the association between poor premorbid functioning and a residual negative symptom syndrome, which may consist of deficit symptoms that persist independent from medication effects (16).

In evaluating premorbid functioning, it is necessary to establish whether poor functioning is an early manifestation of the illness itself or a particular vulnerability characteristic that assists in determining development of the illness, outcome, or symptomatology. The associations between premorbid functioning and negative symptoms found in this study as well as others (34) support either conclusion. However, our data particularly support those of Mukherjee et al. (27), who found that a deterioration in functioning between the periods of childhood and early adolescence was associated with the later presence of negative symptoms. This deterioration in functioning between childhood and early adolescence may be related to late maturation (35), altered myelination processes during late adolescence (36), and the hypothesized faulty synaptic pruning during adolescence (37-39) in schizophrenic patients. Buchanan et al. (25), in their study of the deficit syndrome, observed a similar pattern; differences between subgroups in premorbid functioning became increasingly significant from childhood onward, and the most significant difference occurred in late adolescence ($p=0.008$). This indicates that for some patients, particularly those who will manifest a negative syndrome later on, deterioration in premorbid functioning may represent the onset of the disorder.

Because we found that premorbid variables did not correlate with positive symptoms, it appears that the relationship to deterioration in premorbid functioning is specific to negative symptoms and not schizophrenic

pathology as a whole. Some authors have proposed that negative symptoms may be the more fundamental symptoms of schizophrenia (40) because they show more internal consistency (41). The relationship between premorbid deterioration and severity of negative symptoms supports this conclusion, if we assume that the deterioration in functioning represents an early prodrome of the disorder. It is conceivable that patients with premorbid deterioration have a more gradual onset than those with good premorbid functioning, who may have a more acute onset; this would have to be pursued in a prospective longitudinal design (42) rather than a retrospective cross-sectional study such as this.

A limitation of our study is that all of our subjects were men. Male schizophrenic patients have been shown to have poorer premorbid functioning (43, 44) and poorer treatment response (29, 45, 46) than female schizophrenic patients. There is also an indication that men have more negative symptoms, although this has been difficult to show empirically (34). In addition, it has been proposed that schizophrenia may be the result of a neurodevelopmental disorder and that the prevalence of these disorders are more common in men than women (47, 48). Thus, the relationships we found with the deterioration factor may not have been significant if female patients had been included in the study group. What role these neurodevelopmental abnormalities play in the deterioration of social and intellectual functioning is not fully understood. However, the concurrence of these phenomena is of interest and should be pursued further in a study group consisting of both sexes.

Premorbid functioning and deterioration were correlated significantly with all aspects of negative symptoms except anhedonia-asociality, avolition-apathy, and emotional withdrawal, suggesting that some of these symptoms may be in response to the illness itself. This supports the more restricted definition of negative symptoms suggested by Crow (14), indicating that the only true negative symptoms are those we can distinguish from depression or the side effects of positive symptoms. This finding is particularly interesting because our stability criterion may have eliminated secondary exacerbation effects, thus illuminating this relationship. Further, our inpatient milieu may provide the necessary environmental intervention needed to avoid the confounding effects of lack of stimulation on the negative symptom ratings (12). These aspects of the present study may have controlled some of the variance in negative symptoms and thus strengthen the interpretation of the relationships. Our data indicate that the patients' clinical status and longitudinal observations are important in the assessment of these relationships in studies of negative and positive symptoms.

Our subtyping model exhibited similar relationships to the correlational model, indicating that although viewing negative symptoms as a continuum of pathology is certainly warranted, meaningful subtypes do exist under well-defined clinical conditions such as those in this study. The present data and the deficit versus

nondeficit distinction (16) as well as the Kraepelinian subtype of schizophrenia, which represents severe dysfunction in employment and self-care capabilities (49), suggest that the negative dimension is meaningful in determining diagnosis, treatment, and outcome. Although a cross-sectional evaluation of drug-free patients does give an insight into how residual negative symptoms are, it does not argue that the negative subtype exists longitudinally (4). As such, the significance observed between these subtypes may be an artifact of cross-sectional rather than longitudinal types of analyses (42). Clearly, most of the patients in our study group as well as others (23) have mixed symptoms. However, under these well-defined conditions the dichotomy between positive and negative symptoms provides some insight into the nature and perhaps the origin of the disorder in this group of patients that can be used in future longitudinal studies.

Technique for Training Schizophrenic Patients in Illness Self-Management: A Controlled Trial

Thad A. Eckman, Ph.D., William C. Wirshing, M.D., Stephen R. Marder, M.D.,
Robert P. Liberman, M.D., Kathleen Johnston-Cronk, M.S.,
Karin Zimmermann, Ph.D., and Jim Mintz, Ph.D.

Objective: To determine whether schizophrenic outpatients receiving low-dose neuroleptic therapy could learn and retain complex information and skills related to self-management of their illness, a novel technique of teaching, using cognitive and behavioral methods, was designed to compensate for the patients' learning disabilities. **Method:** The subjects were 41 patients with DSM-III-R schizophrenia who were receiving constant maintenance neuroleptic drug therapy. They were randomly assigned to structured, modularized skills training or to supportive group psychotherapy. **Results:** The patients who received skills training made significant gains in each of the areas taught, while those participating in group therapy did not. The skills learned during training were retained without significant erosion over a 1-year follow-up period. **Conclusions:** The effectiveness of modularized teaching of illness self-management skills to schizophrenic patients appears to be largely independent of baseline psychopathology and symptom improvement. Such an approach is useful for overcoming or compensating for the enduring cognitive and information processing deficits commonly found in schizophrenia.

(Am J Psychiatry 1992; 149:1549-1555)

The public health problems posed by schizophrenia, as well as the personal misery experienced by patients and their families, are amplified by the "revolving door" pattern of multiple rehospitalizations and homelessness, which are so often the consequences of patients' failing to adhere to their treatment regimens (1, 2). Despite more than a quarter century of research evidence for the efficacy of maintenance neuroleptic therapy in reducing relapse rates for patients with chronic schizophrenia, reliable compliance with medication is more the exception than the rule (3, 4).

Consistent with the current emphasis on promoting patients' understanding of their illness and cooperation

with their treatment, skills training has emerged in recent years as an effective technique for psychiatric rehabilitation (5). As a psychosocial adjunct to antipsychotic drug therapy, training schizophrenic patients in social and independent living skills—through individual, group, and family therapies—has yielded improvements in social functioning, reductions in relapse rates, and superior cost-effectiveness (6-9). However, there are considerable obstacles to the generalized use of skills training in schizophrenia and to its specific application to improving patients' grasp of such complex behaviors as monitoring medication effects and identifying prodromal symptoms of relapse. Foremost among the obstacles are the intrusion of persisting and intercurrent symptoms into the learning process (10) and the enduring cognitive deficits that appear to be vulnerability markers in schizophrenia (11). For example, deficits in sustained attention, memory, and executive functioning impair the information processing required for learning complex knowledge and skills (12).

If skills training is to be effective in teaching patients how to be more responsible and reliable consumers of treatment, the training procedures must be designed to overcome or compensate for the enduring cognitive and information processing deficits commonly found in schizophrenia. Furthermore, the training techniques must include ways to overcome the negative symptoms

of schizophrenia, including anhedonia, blunted affect, social withdrawal, lack of motivation, anergia, poverty of speech, and depression (13). A modular form of training in social and independent living skills, designed to counter the symptomatic and cognitive barriers to learning, has been developed by the UCLA Clinical Research Center for Schizophrenia and Psychiatric Rehabilitation and has been field tested in facilities throughout the United States and Canada (14). The present controlled clinical trial examined the efficacy of these modules in teaching skills involved in symptom and medication self-management to schizophrenic outpatients maintained on a low-dose neuroleptic drug regimen.

METHOD

Subjects

The study group was composed of 41 male veterans who met the *DSM-III-R* criteria for schizophrenia according to diagnostic interviews using the Present State Examination to elicit signs and symptoms. Most subjects had had 10 or more years of treatment for schizophrenia and were recruited from inpatient and outpatient units of a U.S. Department of Veterans Affairs hospital. Their mean age was 40 (SD=8.6), and only 27% (N=11) had ever been married. On average, they had 13 years (SD=1.8) of education. Of the 40 subjects for whom ethnic data were available, 14 (35%) were Caucasian, 23 (58%) were black, and three (8%) were Hispanic. Of the 20 patients randomly assigned to skills training, 16 (80%) were unemployed during the entire prior year, compared with 11 (52%) of the 21 patients who received group psychotherapy; this difference was not significant. Other characteristics of the subjects assigned to the two psychosocial treatment conditions are listed in table 1. While the subjects assigned to supportive group therapy had, on average, 13.57 years of education and those assigned to social skills training had an average of 12.15 years, the other variables showed no statistically significant differences between treatment groups.

To qualify for entry into the study, subjects were required to have no evidence of mental retardation or organic brain syndrome, to not be currently abusing alcohol or drugs (as determined by urine toxicologic test-

ing), and to be able to tolerate 5–10 mg of fluphenazine decanoate every other week. This study was nested within a larger project examining the effects of lower than conventional doses of neuroleptic medication. The 41 subjects who participated in the study reported here were those who completed at least 6 months of psychosocial treatment and the full battery of pre- and post-treatment assessments.

Experimental Design

Upon entry into the study, each patient was randomly assigned to either skills training in groups or to supportive group psychotherapy. The subjects were carefully monitored on a weekly basis over the 18-month study period for indications of clinical instability, prodromal symptoms, or exacerbations of their disorder. Depending on their clinical states, the subjects received time-limited oral fluphenazine or placebo supplementation of their 5–10-mg biweekly fluphenazine decanoate until the prodrome or exacerbated state was controlled. Over the course of the 18 months there was no significant difference in cumulative fluphenazine dose between the subjects receiving skills training and those receiving group therapy.

The study was a repeated measures design comparing two psychosocial interventions at four time intervals—pretreatment baseline, posttreatment, and 6- and 12-month follow-ups. In addition to the designated psychosocial treatments (to be described), all subjects received case management, psychiatric services, and ancillary medical and social services as needed in the research outpatient clinic of the hospital. The subjects attended the clinic at least biweekly, receiving their depot injections and clinical status evaluations from the clinic nurse, social worker, and psychiatrists.

Treatments

Group psychotherapy. These subjects engaged in an insight-oriented and supportive group process that was leavened with abundant information and education about schizophrenia as an illness and the importance of adhering to prescribed treatments. While of necessity there was discussion of medication and symptom management, no structured curriculum was followed and no formal behavioral techniques were used. The group could be best described as aiming for individual and personal goals encouraged through exploratory and supportive leadership. The group was led by a psychologist with more than 6 years of experience in leading therapy groups of patients with chronic schizophrenia. During twice-weekly 90-minute sessions, the group members discussed problems encountered in daily living and in their social relationships. Mutual understanding, social support, and group cohesion were emphasized. The subjects were encouraged to offer suggestions and explore solutions to the problems raised by one another. The therapist used customary group therapy techniques, such as open-ended questions, re-

TABLE 2. Skill Areas and Learning Objectives in the Medication Management and Symptom Management Modules of the UCLA Social and Independent Living Skills Program

Module	Skill Areas	Learning Objectives
Symptom management	Identifying warning signs of relapse	To identify personal warning signs
	Managing warning signs	To monitor personal warning signs with assistance from other people To obtain assistance from health care providers in differentiating personal warning signs from persistent symptoms, medication side effects, and variations in mood; to develop an emergency plan for responding to warning signs
	Coping with persistent symptoms	To recognize and monitor persistent personal symptoms; to obtain assistance from health care providers in differentiating persistent symptoms from warning signs, medication side effects, and variations in mood; to use specific techniques for coping with persistent symptoms
	Avoiding alcohol and street drugs	To monitor persistent symptoms daily To identify the adverse effects of alcohol and illicit drugs and the benefits of avoiding them; to refuse offers of alcohol and street drugs; to know how to resist using these substances in coping with anxiety, low self-esteem, or depression; to discuss openly use of alcohol and drugs with health care providers
Medication management	Obtaining information about antipsychotic medication	To understand how these drugs work, why maintenance drug therapy is used, and the benefits of taking medication
	Knowing correct self-administration and evaluation	To follow the appropriate procedures for taking medication; to evaluate responses to medication daily
	Identifying side effects of medication	To know the specific side effects that sometimes result from taking medication and what to do when these problems occur
	Negotiating medication issues with health care providers	To practice ways of obtaining assistance when problems occur with medication

flection, warmth and concern, and empathic understanding. After the first 6 months, the group continued to meet an average of once per week through the 1-year follow-up period.

Modular skills training. Two modules from the UCLA Social and Independent Living Skills Program (15) with highly prescribed curricula for teaching medication and symptom self-management were used in the twice-weekly group skills training sessions during a 6-month period. Each module consisted of a clinician's manual, a patient's workbook, and a videotape that demonstrated the skills to be learned. The skill areas for the two modules are listed in table 2 and represent the main goals of the program.

The modular procedures were designed to compensate for the cognitive and symptomatic interference with learning commonly found in schizophrenia. The patients proceeded through each skill area in a sequence of seven learning activities and exercises, starting with an introduction that highlighted the values and advantages of the training. The introduction used cognitive restructuring principles that, combined with the abundant positive social reinforcement delivered by the group leader throughout all learning activities, aimed to overcome the lack of motivation experienced by many schizophrenic patients. The next two learning activities—video modeling and behavioral rehearsal or role playing—were designed to engage the patients' attention and participation through the use of graphic demonstrations, maximal success experiences, and video feedback. Focused instructions, prompting, and coaching with immediate positive feedback were aimed at overcoming the obstacles to learning that arise from psychopathology and cognitive deficits.

The fourth and fifth learning activities were intended

to teach patients how to cope with frequently encountered obstacles to performing their newly acquired skills in their natural environments. The resource management activity was designed to teach patients how to gather the resources necessary for implementing a particular skill; for example, access to a telephone for making a clinic appointment and access to transportation were prerequisites for using the skills regarding negotiations about medication problems with their doctors or seeking early intervention to prevent a relapse. The outcome problem-solving activity taught patients how to respond when the environment failed to provide the expected and desired outcome after their performance of a particular skill. For example, if an individual got to the clinic to report a medication side effect or the emergence of warning signs of relapse, it was important to know how to handle the exigency of the doctor's having been called away on an emergency or being sick that day. Through repeated practice exercises, these two learning activities were intended to teach patients a general problem-solving strategy for illness self-management and to overcome the inadequacies in social problem solving and self-assertiveness so frequently noted in schizophrenic patients.

The final two learning activities—in vivo exercises and homework assignments—were used to facilitate the transfer of training to the patients' living environments. In each of these activities, the group leader helped the patients to fine-tune their performances, resulting in more independent action. Training sessions for both modules were scheduled twice weekly for 6 months, and each module took approximately 90 minutes per session. Training continued until all patients achieved the specified mastery criterion of 80% of the skills, as determined by role-playing tests. After the 6 months of

FIGURE 1. Attainment and Retention of Skills in Medication and Symptom Management by Schizophrenic Patients Receiving Skills Training or Group Psychotherapy^a

^aSignificant effect of training for patients receiving social skills training (medication management: $F=75.10$, $df=1, 34$, $p<0.0001$; symptom management: $F=36.23$, $df=1, 32$, $p<0.0001$). Significant difference between groups in medication management skills at 6 and 12 months ($F=56.45$, $df=1, 30$, $p<0.0001$, and $F=40.28$, $df=1, 25$, $p<0.0001$, respectively), and significant difference between groups in symptom management skills at 6 and 12 months ($F=6.34$, $df=1, 28$, $p<0.02$, and $F=9.41$, $df=1, 22$, $p<0.005$, respectively).

training in these two modules, the subjects in this condition continued to meet for the remainder of the 1-year follow-up period once a week in a basic social skills training group (5) aimed at individual goal setting and interpersonal problem solving.

Assessment Measures

All subjects were evaluated with the Brief Psychiatric Rating Scale (BPRS) and the Schedule for Assessment of Negative Symptoms (16) at baseline and at regular monthly intervals thereafter. The BPRS ratings were performed by experienced clinicians who had been trained until they reached an interrater reliability of 0.80 (intraclass r) or greater. Although attempts were made to keep the raters blind to the subjects' psychosocial treatment conditions, a few patients revealed this information during the rating sessions.

Skill attainment was assessed through the subjects' behavioral performances in a series of standardized role-playing tests. Seven scenes taken from the essential skill areas of the medication management and symptom management modules were administered, and the patients' performances were rated on a 4-point Likert-type scale ranging from "poor" to "excellent." Each point on the scale was defined operationally and included verbal content and nonverbal and paralinguistic skills relevant to each of the skills that were taught in the modules. Ratings of each scene were summed to yield a total score reflecting the acquisition of skills for each module. Role-playing tests have been shown to be valid means of assessing the social competence of patients with schizophrenia or major affective disorders (17).

The skill assessments (14) were made by research assistants who were initially trained to reliably rate the role-playing tests by practicing independently with clinic patients not participating in the study until each behavioral category was rated at or above 0.80; the standard rating by which the assistants were judged was made by the first author. Subsequently, interrater reliability was assessed and maintained through joint ratings of 15% of the tests in which the first author was the criterion rater. Interrater reliability remained high throughout the study, ranging between 0.82 and 1.00 (kappa coefficients).

RESULTS

Because attrition occurred during the 12-month follow-up period, most but not all subjects were rated on the skill levels at each rating point. Over the full 18-month study period, more subjects in the skills training condition (15 of 20) than in the supportive group therapy (12 of 21) remained in the study; this difference almost reached statistical significance. The psychiatric and social histories, pretreatment BPRS scores, and pretreatment scores on the skills tests did not differentiate the subjects who dropped out from the subjects who completed the intensive treatment and full follow-ups.

Group by Trial analyses of variance were used to evaluate skills acquisition in the two psychosocial treatment conditions. As shown in figure 1, there was a significant effect of training in both modules for the subjects who received the social skills training but not for the subjects in group therapy. The pretreatment mean skill levels for the two psychosocial conditions were virtually identical, while the posttreatment means diverged considerably, indicating that the subjects who received modular skills training displayed a marked increase in knowledge and skill and the subjects in group therapy did not improve in these domains.

The durability of learning over time was evaluated by comparing the posttreatment means with the 6-month follow-up means and then comparing the 6-month follow-up means with the means at the 12-month follow-

FIGURE 2. Relationship Between Baseline BPRS Total Score and Subsequent Medication and Symptom Management Skills for Schizophrenic Patients Receiving Skills Training or Group Psychotherapy

up. As depicted in figure 1, for both modules there was little erosion of skill levels during the 12-month follow-up period. The 6-month follow-up means for the subjects in skills training paralleled their posttreatment means and were significantly different from the means of the subjects receiving group therapy. Of interest was the modest, albeit nonsignificant, increase in skills shown by the subjects in group therapy over the 1-year follow-up period.

Do Psychotic Symptoms Impede Learning of Skills?

Analyses were conducted to determine whether cognitive deficits, negative symptoms, and other measures of psychopathology interfered with the patients' acquisition of the knowledge and skills contained in the modules. In particular, we hypothesized that 1) patients rated high on conceptual disorganization and on the negative symptom subscales of the BPRS would show impaired learning in the two modules but that 2) subjects with mild to moderate levels of thought disorder and negative symptoms would learn well.

In the skills training condition, however, there was no relationship between the baseline levels of psychopathology and posttreatment knowledge and skill in medication and symptom management. As depicted in

TABLE 3. Correlations Between Baseline BPRS Scores and Posttreatment Skill Levels for 20 Schizophrenic Patients Receiving Skills Training

Baseline BPRS Measure	Correlation (r) With Posttreatment Skills	
	Medication Management	Symptom Management
Total score	-0.01	-0.40
Positive symptom scores	-0.05	-0.37
Hallucinations	-0.14	-0.24
Unusual thought content	-0.06	-0.51 ^a
Conceptual disorganization	0.14	-0.01
Negative symptom scores	-0.15	-0.21
Blunted affect	-0.29	-0.30
Emotional withdrawal	0.07	-0.17
Motor retardation	0.12	0.27
Median correlation	-0.06	-0.21

^ap=0.03 (df=18).

figure 2, the patients who received skills training performed well on the posttreatment assessments of knowledge and skills regardless of the initial level of psychopathology. Correlations between the initial BPRS ratings and posttreatment skill levels are presented in table 3 for the patients in the skills training condition. While the relationships between symptoms and skills acquired were in the expected negative direction in 14 of the 18 correlations, the one statistically significant correlation was well within what would be expected by chance. Nor were there any significant relationships between mean levels of psychopathology over the 18-month study period and the durability of skills. It should also be pointed out that the subjects in the skills training condition acquired substantial knowledge and skills from their participation in the modules even though they were somewhat more clinically ill at the start of treatment than their counterparts who received group therapy—their symptoms on the BPRS were higher but not statistically so.

The ability of the modular training to effectively overcome obstacles to learning posed by psychopathology and social disability was also seen in the lack of positive correlations between baseline and posttreatment skill and knowledge levels among the subjects in the skills training condition, as well as between baseline ratings of overall work and social functioning and amount of skills learned. The failure to find associations between the subjects' baseline amount and quality of social skills and functioning and their acquisition of knowledge and skills from the modules suggested that the skills training modules could override pretreatment levels of social adjustment in producing a learning effect.

Does Skills Training Displace Psychopathology?

Across the entire pool of subjects in both psychosocial treatment conditions, significant symptom improvements occurred from baseline to the point where pharmacotherapy had stabilized the subjects and they began their participation in either skills training or

group therapy. Symptomatic improvement continued through the 6-month follow-up period. The mean BPRS scores across the entire group were 36.2 (SD=10.6) at intake, 31.2 (SD=8.6) at the start of the psychosocial treatments, and 28.6 (SD=7.9) at the 6-month follow-up ($F=9.77$, $df=2, 35$, $p<0.0004$). Likewise, across the entire pool of subjects the mean score on the Schedule for Assessment of Negative Symptoms fell from 1.02 (SD=0.53) at the start of psychosocial treatment to 0.82 (SD=0.43) at the end of 6 months of psychosocial treatment ($F=6.31$, $df=1, 30$, $p<0.018$).

The subjects in both psychosocial treatment conditions improved substantially from baseline to the end of the period of intensive therapy. Although the subjects in the skills training condition improved somewhat more in terms of total BPRS symptoms, this difference in improvement rates was not significant ($F<1$, $df=1, 36$, *n.s.*) and could be attributed to the somewhat higher initial levels of psychopathology experienced by the subjects randomly assigned to the skills training condition. Similarly, the subjects in the skills training condition did not improve significantly more on negative symptoms than their counterparts receiving group therapy ($F<1$, $df=1, 29$, *n.s.*).

DISCUSSION

The use of structured learning and cognitive therapy in the design of modules to teach illness self-management skills appeared to be instrumental in achieving high levels of knowledge and skill in schizophrenic patients. The substantial and sustained learning of medication and symptom self-management skills by patients could not be simply ascribed to the patients' immersion in an active and educationally oriented outpatient clinic, as comparison patients receiving the same overall clinic treatment and group therapy in lieu of skills training did not show significant learning effects. It is of interest, however, that the frequent interactions with positive and engaging clinicians did have an educational impact on the comparison group patients, since their knowledge and skills showed a small but distinct upward trend over the 18 months of their participation in the study. The impressive learning effects found in this study cannot be secondary to symptom improvements since the patients in the group therapy condition showed significant symptomatic improvements without a corresponding acquisition of knowledge and skills.

The correlations between baseline ratings of psychopathology and subsequent skills performance were relatively small. The patients appeared to be able to learn substantially, regardless of initial psychopathology. It was encouraging that the modules, purposely designed to provide a special educational milieu for cognitively and symptomatically impaired schizophrenic patients, did appear to override these impairments and achieve their intended educational effects. These findings replicate and extend those reported by Mueser et al. (18), who found no relationship of symptoms to changes in

skills among 55 schizophrenic patients enrolled in social skills training.

The ability of the modules to compensate for the patients' cognitive and symptomatic impairments must be qualified by the nature of the subject group; that is, the participants in this study were selected and survived the training because they were relatively stable ambulatory patients with only moderate levels of psychopathology. For example, one subject who had extremely high negative symptoms at the start of treatment learned poorly. As veterans, the subjects in this study had higher premorbid levels of social adjustment than nonveteran schizophrenic subjects might be expected to have, and, thus, generalizations to more disabled populations of schizophrenic patients should be made cautiously. Another caveat came from the social skills trainers in this study, who reported that more arduous training efforts were required to impart knowledge and skills to the more symptomatic patients. For example, patients with higher levels of preoccupying delusions or thought disorder required substantially more repetition and between-session review to sustain their progress.

The learning effects were robust, resisting erosion over the 12-month follow-up period, during which time only a single "booster" session was required to maintain the patients' knowledge and skills at their post-training levels. Also reflecting the robustness of the learning effects of the modules were the lack of correlations between amount of knowledge and skills acquired and sociodemographic and baseline clinical variables, including duration of illness, number of previous hospitalizations, and premorbid social adjustment. This means that the training design was able to "mainstream" patients through the educational modules, much as our public school system often succeeds in mainstreaming normal and handicapped children from widely varied backgrounds in classrooms. Concerns that social skills training might be overstimulating or stressful for vulnerable schizophrenic patients were allayed by findings that scores on indexes of stress and tension, such as the BPRS subscales for anxiety, depression, and distractibility, actually diminished as training was delivered.

Despite the strengths of the present study (clear specification of the intervention, use of state-of-the-art measures for diagnosis and clinical assessment, generally blind and independent assessments, and use of a randomized comparison group that included a control for contact time), questions may be raised about the generalization of the skills and knowledge learned in the modules into patients' real-life circumstances. While formal testing is still being conducted to assess generalization over time and across settings, anecdotal reports by patients and people close to them revealed that nearly all of the patients systematically and regularly monitored their warning signs throughout the time that the modules were being taught—6 months. Many patients routinely brought their medication self-evaluation forms to appointments with their psychia-

trists for review. In one case, a patient taught his schizophrenic roommate how to monitor medication effects by using forms he had obtained during module training because the patient was disturbed by the roommate's erratic behavior, which the patient attributed to poor medication compliance.

A unique feature of the skills training modules used in this study was the video-mediated educational process, which for a wide variety of patient education purposes has been shown to consistently raise short-term knowledge, even among patients with poor literacy skills (19). Future extensions of this technology may be found in video disk, computer-assisted instruction that can reinforce learned constructs, provide immediate feedback, and promote cognitive rehearsal. These technological advancements can be programmed for interactive learning, individualized, and presented at times more convenient for the patient (20).

Alprazolam Plasma Concentrations and Treatment Response in Panic Disorder and Agoraphobia

Ira M. Lesser, M.D., R. Bruce Lydiard, Ph.D., M.D., Edward Antal, Ph.D., Robert T. Rubin, M.D., Ph.D., James C. Ballenger, M.D., and Robert DuPont, M.D.

Objective: The authors' goal was to evaluate the relationship between plasma concentrations of alprazolam and both treatment response and side effects in patients with panic disorder and agoraphobia. **Method:** Ninety-six patients with panic disorder and agoraphobia were treated at three sites in a 6-week, fixed-dose, double-blind, placebo-controlled, dose-response study of 2 mg/day or 6 mg/day of alprazolam. Assessments were made of panic attacks, avoidance behavior, generalized anxiety, and global response. Blood samples were collected throughout the study and analyzed for alprazolam and other benzodiazepines. **Results:** Patient compliance with the protocol was judged to be good on the basis of plasma concentrations. According to logistic regression analysis, the relationships between plasma alprazolam concentration and response, as reflected by number of panic attacks reported, phobia ratings, physicians' and patients' ratings of global improvement, and the emergence of side effects, were significant. However, there was no significant relationship between plasma alprazolam concentration and the degree of generalized anxiety symptoms. **Conclusions:** The authors conclude that plasma concentration of alprazolam is related to treatment response, particularly in panic attacks. The alprazolam concentration associated with treatment response or with emergence of a given side effect varied widely among individuals, highlighting the necessity for individualized dose adjustment to obtain optimal treatment response while minimizing side effects.

(Am J Psychiatry 1992; 149:1556-1562)

Studies of the triazolobenzodiazepine alprazolam in the treatment of panic-related disorders have repeatedly demonstrated the efficacy of this compound, but they have indicated that a wide range of doses may be necessary for control of panic attacks (1-4). This wide range could be due to a number of factors that are not mutually exclusive, such as 1) pharmacokinetic variability, resulting in variable alprazolam plasma concentrations from a given dose, 2) differences in severity of the panic-related disorder, 3) intersubject vari-

ability in response to alprazolam, and 4) self-medication with other benzodiazepines.

Intersubject differences in alprazolam pharmacokinetics may be a major factor in the variability of effective dose, since administration of the same dose to homogeneous patient samples can result in a three- to four-fold variability in steady-state plasma alprazolam concentration (3, 5). Although the results of previous studies have demonstrated a relationship between alprazolam dose and plasma concentration (6, 7), the relationship between alprazolam plasma concentration and clinical outcome has not been clearly elucidated.

The present study was a three-site, placebo-controlled trial. It was undertaken to evaluate the relationships between alprazolam dose, plasma concentration, and treatment response in patients with panic disorder. A fixed-dose study design was used to evaluate a relatively low and a relatively high dose of the drug. This design may be more appropriate for evaluating relationships between concentration and treatment response (8) than the adjustable-dose design used in previous alprazolam efficacy studies. This report presents the analysis of the relationship between treatment response measures and plasma alprazolam levels in pa-

tients with panic disorder who were receiving 2 mg/day of alprazolam, 6 mg/day of alprazolam, or placebo.

We also address the use of plasma benzodiazepine concentrations to assess protocol compliance. Efficacy and side effect results from the study have been reported elsewhere (9). A preliminary report on the logistic regression methodology also has been presented elsewhere (10), and the concentration data obtained from that study have been used to evaluate the feasibility of subjecting clinical efficacy trial data to population pharmacokinetic analyses (11).

METHOD

Patients and Study Design

The complete study design, including details of patient recruitment and screening and descriptions of the clinical evaluation scales and diagnostic criteria, has been described in a previous report (9). In brief, this was a double-blind, placebo-controlled, fixed-dose study evaluating placebo, 2 mg/day of alprazolam, and 6 mg/day of alprazolam. The subjects were 96 patients who met *DSM-III* criteria for panic disorder or agoraphobia with panic attacks after evaluation with the Structured Clinical Interview for *DSM-III*, Upjohn Version (12). Seventy percent of the subjects were women and 30% were men; their mean age was 37.1 years. From 77% to 90% in each treatment group met criteria for agoraphobia (the difference among the groups in the proportion of patients with agoraphobia was not significant). The protocol was approved by the institutional review board of each study site, and all subjects gave written informed consent before participating in the trial.

After diagnostic, medical, and laboratory examinations were completed, subjects were randomly assigned to three treatment groups: 30 were given 2 mg/day of alprazolam, 31 were given 6 mg/day of alprazolam, and 35 were given placebo. The groups were comparable in age; there were more male subjects in the group given 2 mg/day of alprazolam. A psychotropic drug washout period of at least 1 week preceded the baseline evaluation. Patients then received either placebo or 1 mg/day of alprazolam, with a dose escalation schedule ensuring that the target dose was achieved by day 3 for the patients given 2 mg/day and by day 18 for the patients given 6 mg/day. The trial lasted 6 weeks and was followed by a 3-week drug taper. Evaluations were performed at baseline and after 1, 2, 3, 4, and 6 weeks of treatment; 15 (45.5%) of the patients given placebo, 23 (76.7%) of the patients given 2 mg of alprazolam, and 16 (48.4%) of the patients given 6 mg of alprazolam completed the 6-week trial. The methods of dealing with this differential dropout rate are discussed later in this paper and elsewhere (9).

Blood samples were obtained from the subjects at each evaluation time. In addition to the times blood was drawn, the actual times the medication or placebo was administered on the day of sampling and the previous

TABLE 1. Criteria for Classification of Response to Alprazolam Treatment for Panic Disorder

Measure of Treatment Response	Response Classification		
	Major	Moderate	None
Reduction from baseline in total number of panic attacks (%)	>75	25–75	<25
Reduction from baseline in Hamilton anxiety score (%)	>50	25–50	<25
Overall phobia score	0–3 ^a	4–6 ^b	7–10 ^c
Change from baseline in main phobia fear and avoidance score (%)	>50	25–50	<25
Change from baseline in agoraphobia fear and avoidance score (%)	>50	25–50	<25
Physician-rated global improvement scale score	9–10 ^d	7–8 ^e	0–6 ^f
Patient-rated global improvement scale score	9–10 ^d	7–8 ^e	0–6 ^f

^aNot at all to mildly anxious.

^bModerately anxious.

^cMarkedly to extremely anxious.

^dMarkedly improved or back to normal.

^eModerately improved.

^fWorse to a little better.

day were recorded. To generate a random selection of collection times after the previous alprazolam dose, no time of blood sample collection was specified within the protocol. Ten-ml blood samples were collected in heparinized tubes and centrifuged, and the plasma was separated and frozen until analysis.

Benzodiazepine Assays

Plasma samples from all patients were analyzed for not only alprazolam but also diazepam and desmethyldiazepam to determine if patients were medicating themselves with other benzodiazepines (excluding lorazepam). Alprazolam, diazepam, and desmethyldiazepam concentrations were determined by gas-liquid chromatography with electron-capture detection by previously reported methods (13, 14).

Data Analysis

Treatment response measures. Treatment response was classified for each of the following efficacy measures: total number of major panic attacks per week, total score on the Hamilton Rating Scale for Anxiety (15) (used to measure overall anxiety, apart from specific panic attacks), overall phobia rating, fear and avoidance factors of the main phobia and agoraphobia ratings derived from the work of Marks and Mathews (16), physician-rated global improvement scale score, and patient-rated global improvement scale score. We defined categories of major, moderate, or no response for each measure, as shown in table 1.

Logistic regression analysis. The relationship between treatment response and plasma alprazolam concentrations was examined with logistic regression analysis (17, 18) of data from the three treatment groups. Patient response classification and plasma alprazolam

FIGURE 1. Mean Plasma Alprazolam Concentrations of Patients With Panic Disorder Given 2 mg/day or 6 mg/day

*Significant difference between groups at week 2 ($t=3.86$, $df=52$, $p=0.0003$), week 3 ($t=6.02$, $df=49$, $p=0.0001$), week 4 ($t=7.04$, $df=47$, $p=0.0001$), and week 6 ($t=6.63$, $df=37$, $p=0.0001$).

concentrations were fitted to a logistic response function with the CATMOD procedure of the Statistical Analysis System (19). Regression coefficient estimates generated from the fitting procedure then were used to calculate the probability of a patient's having a particular response (e.g., major, moderate, none) at a given alprazolam plasma concentration. The details of the analysis have been reported elsewhere (10).

RESULTS

Data for some of the 96 patients could not be included in some of the analyses due to the incompleteness of concentration and/or response data. The number of individuals for whom data were analyzed by each method is reported in each analytical section.

Compliance With Treatment

Only one patient in the placebo group had a positive alprazolam level at any evaluation time; this patient had a positive level at week 2. At baseline, six (20%) of the 30 placebo patients for whom this information was available had positive diazepam levels, and nine (30%) had positive desmethyldiazepam levels. The percent of placebo patients with positive levels for diazepam and/or desmethyldiazepam remained relatively constant throughout the study.

No patients given either 2 mg or 6 mg of alprazolam treatment for whom this information was available ($N=55$) had a positive alprazolam level at baseline. After therapy was initiated, positive alprazolam levels were detected in virtually all alprazolam-treated patients (96%–100% at different evaluation times). At baseline, nine (33%) of the available 27 patients given 2 mg/day of alprazolam and five (18%) of the available

28 patients given 6 mg/day of alprazolam had detectable diazepam and/or desmethyldiazepam concentrations. These percentages decreased during the study; at week 6 only two (8.7%) of 23 patients given 2 mg/day of alprazolam and one (6.2%) of 16 patients given 6 mg/day had detectable levels.

Mean Plasma Alprazolam Concentrations

Alprazolam plasma concentration data were available for 61 patients treated with alprazolam (30 of the patients given 2 mg/day and 31 of the patients given 6 mg/day). On average, each subject had four plasma level determinations. The majority of the samples were collected between 0 and 6 hours after medication administration. Mean plasma alprazolam concentrations for the two alprazolam treatment groups at each week of evaluation are shown in figure 1. Alprazolam concentrations differed significantly between the patients given 2 mg/day of alprazolam and those given 6 mg/day at weeks 2, 3, 4, and 6 (figure 1). At week 4, when all patients had been receiving their maximum alprazolam dose for at least 9 days, the mean alprazolam concentrations were 24.5 ng/ml ($SD=15.6$) for the patients given 2 mg/day and 65.2 ng/ml ($SD=24.4$) for the patients given 6 mg/day. Only 10% of the patients given 2 mg/day had plasma levels above 40 ng/ml, and none had a plasma level above 80 ng/ml. Conversely, approximately 80% of those given 6 mg/day had plasma levels above 40 ng/ml.

Response Relationship to Alprazolam Plasma Concentration

Data from the last evaluation period in the three treatment groups were analyzed by logistic regression. This is roughly equivalent to a week-6 endpoint-imputed analysis (i.e., the last observation was carried forward). The mean times of the last evaluations were 4.8 weeks ($SD=1.6$) for the placebo group, 5.1 weeks ($SD=1.2$) for the patients given 2 mg/day of alprazolam, and 4.8 weeks ($SD=1.4$) for the patients given 6 mg/day of alprazolam (there were more dropouts among the patients given placebo and those given 6 mg/day than among the patients given 2 mg/day). At these evaluation times, all patients were receiving their scheduled alprazolam dose except for three patients in the 6 mg/day group who had reached a dose of only 4 mg/day. These patients were included in the analysis because plasma concentration, not dose, was being evaluated as a predictor of response.

Number of Major Panic Attacks

At baseline, the mean number of panic attacks per week was 7.5 ($SD=9.9$) for the placebo group, 5.3 ($SD=4.9$) for the patients given 2 mg/day of alprazolam, and 6.6 ($SD=7.7$) for the patients given 6 mg/day of alprazolam. Among patients who completed the 6-week trial, the mean number of panic attacks per week

was 3.7 (SD=4.9) for the placebo group, 1.0 (SD=2.7) for the patients given 2 mg of alprazolam, and 1.0 (SD=2.8) for the patients given 6 mg of alprazolam. According to endpoint analysis, the mean number of panic attacks per week was 5.4 (SD=6.2) for the placebo group, 2.0 (SD=4.6) for the patients given 2 mg/day of alprazolam, and 1.9 (SD=3.9) for the patients given 6 mg/day of alprazolam. Both treatment groups improved more than the patients given placebo (9).

Plasma alprazolam concentration was a significant predictor of response assessed by the reduction of major panic attacks ($\chi^2=70.58$, $df=90$, $p=0.003$, likelihood ratio=0.935). A steady-state plasma alprazolam concentration of 15 ng/ml was necessary to achieve a 50% probability of being classified as a major responder, and a concentration of 48 ng/ml was necessary to achieve a 75% probability of being a major responder.

The calculated probability curves, based on the best-fit parameter estimates from the logistic regression model, and the actual response frequencies are presented in figure 2. The three individual graphs represent the predicted probabilities for responder classification over a range of drug concentrations for the three categories of response: major (greater than 75% reduction in panic attacks), moderate (25%–75% reduction), and none (less than 25% reduction). From these graphs, one can determine the probability of attaining the level of response associated with a particular alprazolam steady-state concentration by selecting the concentration and reading the numerical value associated with the curve at that concentration on the respective response graph of interest. At any given alprazolam concentration, the sum of the three probability values for the response classifications equals one.

Using the more stringent criterion for treatment response of having no panic attacks at the last visit, we found that 18 (67%) of 27 subjects with alprazolam concentrations greater than 40 ng/ml, eight (57%) of the 14 subjects with concentrations between 20–40 ng/ml, and eight (42%) of the 19 subjects with concentrations less than 20 ng/ml met this criterion.

Hamilton Rating Scale for Anxiety

Logistic regression analysis showed no significant relationship between steady-state alprazolam plasma concentration and response classified on the basis of change in Hamilton anxiety score. According to this scale, approximately 70% of the patients were classified as either major or moderate responders at the lowest alprazolam concentrations.

Phobia Ratings

The five phobia ratings were 1) the overall phobia rating, 2) the main phobia fear score, 3) the main phobia avoidance score, 4) the agoraphobia fear score, and 5) the agoraphobia avoidance score. Alprazolam plasma concentration was a significant predictor for response based on the main phobia fear score ($\chi^2=76.24$,

FIGURE 2. Calculated Probability Curves and Observed Frequencies of Patients With Major, Moderate, or No Response to Alprazolam for Panic Disorder

$df=76$, $p=0.04$, likelihood ratio=0.471) and the agoraphobia fear score ($\chi^2=78.4$, $df=76$, $p=0.03$, likelihood ratio=0.403). However, the actual response frequencies on these scales varied considerably and inconsistently with increasing alprazolam concentrations. Therefore, the probability values should be interpreted cautiously. An alprazolam concentration of approximately 75 ng/ml was necessary to obtain a 50% probability of a patient's being classified as a major responder (greater than 50% reduction) by the main phobia fear score. The numbers of patients classified in each response group are presented in table 2. There were no significant relationships between response classification and plasma alprazolam concentration for the other three phobia ratings.

Physician-Rated and Patient-Rated Global Improvement Scales

There was a significant relationship between plasma alprazolam concentration and treatment response cate-

TABLE 2. Relation of Plasma Alprazolam Concentrations and Response Rates for Patients With Panic Disorder

gorized according to the physician-rated ($\chi^2=104.3$, $df=90$, $p=0.002$, likelihood ratio=0.143) and patient-rated ($\chi^2=94.46$, $df=90$, $p=0.02$, likelihood ratio=0.353) global improvement scales. Again, actual response frequencies did not consistently increase with increasing alprazolam concentrations. According to the calculated curve, the steady-state alprazolam plasma concentration necessary to result in a 50% probability of a patient being classified as a major responder (markedly improved or back to normal) on the physician-rated global improvement scale was 63 ng/ml. However, this finding should be interpreted cautiously because the actual frequencies of a major response on the physician-rated global scale rating varied widely as shown in table 2. The corresponding levels of response at the same concentration levels for the patient-rated global scale also are shown in table 2.

Treatment-Emergent Side Effects and Symptoms

Treatment-emergent symptoms and side effects were defined as those having a greater severity at the time of evaluation than at baseline. Seven of 42 symptoms were reported more frequently by patients given either 2 mg/day or 6 mg/day of alprazolam: sedation/drowsiness, ataxia/impaired coordination, slurred speech, nasal congestion, constipation, diarrhea, and decreased libido (9). Of these, more patients given 6 mg/day than patients given 2 mg/day reported ataxia/impaired coordination and slurred speech; similar numbers reported the remaining symptoms. Five of 42 symptoms (impaired mentation, insomnia, tachycardia/palpitations, tremor, and excessive sweating) were reported more frequently by patients given placebo (9).

The relationships between alprazolam concentration and the emergence of seven significantly and positively related symptoms and side effects were examined by logistic regression analysis of the data from week 4 and

the last evaluation visit. Similar results were obtained for both evaluations (table 3). At week 4, in addition to the symptoms and side effects listed in table 3, the emergence of tachycardia, a symptom of panic disorder, was significantly related to alprazolam concentrations; however, the probability of its emergence was greatest at low alprazolam concentrations.

DISCUSSION

Patient compliance with the protocol was judged to be good. The majority of patients took the study medications and refrained from medicating themselves with other benzodiazepine agents, and this was confirmed by obtaining plasma drug concentrations (although we did not measure concentration of lorazepam). This finding is essential to the further analyses of correlations between alprazolam concentration and response.

The doses in this study were selected on the basis of preliminary data indicating that doses of 2 mg/day and 6 mg/day of alprazolam should result in a wide range of steady-state plasma alprazolam concentrations and that more patients given 6 mg/day would respond to therapy (3, 4). The expected range and overlap of plasma alprazolam concentrations were achieved, and the two doses resulted in significantly different mean alprazolam concentrations. Thus, the selected doses resulted in data suitable for logistic regression analyses.

The results of our study demonstrate that patient response measured according to multiple dimensions is significantly related to steady-state plasma alprazolam concentrations. For panic attacks, the probability of a subject being classified as having a major, moderate, or no response was significantly and positively related to steady-state plasma alprazolam concentration. In a previous report (11), a pharmacokinetic analysis of the data obtained from the same patients showed that the

elimination of alprazolam in the patients who had major or moderate responses was approximately 40% less than that in the patients demonstrating no response. Reduced elimination of alprazolam resulted in higher steady-state plasma alprazolam concentrations for a given dose in patients classified as responders. This finding further supports a relationship between concentration and response.

Previous work indicates that there is an approximate relationship of 1 mg/day alprazolam dose to 10 ng/ml alprazolam steady-state concentration (7); our findings agree with this ratio. Therefore, the practitioner could then use our finding of a relationship between response and plasma concentration, based on logistic regression analysis, as a guide to total daily dose. For example, for panic attacks, a 75% probability of having a major response occurred at 48 ng/ml, roughly translating to a dose of 4–5 mg/day of alprazolam (given the caveats about intersubject variability). At approximately 1–2 mg/day alprazolam, there was a 50% probability of a major response for panic attacks. Ciraulo et al. (7) reported that, on global measures of impairment, significant improvement in subjects with panic disorder was achieved at plasma concentrations of 20 ng/ml and maximum response occurred at concentrations of 60 ng/ml and higher. However, Ciraulo et al. did not report information regarding response of specific symptoms. In our study, according to physician-rated and patient-rated global improvement scales, 53% of the subjects achieved a moderate response at 20 ng/ml and 80% at 60 ng/ml, which is similar to the data of Ciraulo et al. (7).

Plasma alprazolam concentration in our patients was not a significant predictor of treatment response based on Hamilton anxiety scores, probably due to the fact that the majority of patients with low alprazolam concentrations were classified as major responders on this outcome measure. In fact, only about 10% of patients with alprazolam concentrations between 20 ng/ml and 80 ng/ml were nonresponders on the Hamilton Rating Scale for Anxiety. Clinically, this means that most of the improvement in Hamilton anxiety scores (indicating more generalized or intercurrent anxiety symptoms) in these patients occurred at low doses and low plasma concentrations of alprazolam.

These results suggest that significant improvement in panic attacks occurs at higher alprazolam concentrations than those required for improvement in concomitant anxiety. Although there was clearly a reduction in panic attacks at lower alprazolam concentrations, higher concentrations increased the likelihood of being panic-free at the end of the trial. This is consistent with our previous finding that, although there were no significant differences in reduction of total panic attacks per week between the patients given 2 mg/day and those given 6 mg/day, there were significantly more patients who were panic-free among the patients given 6 mg/day (9).

Still higher concentrations of alprazolam were necessary to achieve a significant reduction in phobias. For the agoraphobia and main phobia fear scores, concen-

TABLE 3. Alprazolam Concentrations Associated With 50% Probability of Side Effects^a

Side Effect	Alprazolam Concentration (ng/ml) Associated With 50% Probability of Emergence	
	Week 4	Last Evaluation Period
Sedation	40	45
Ataxia	70	70
Memory problems	95	90
Slurred speech	100	90
Fatigue	120	110
Decreased libido	120	110
Sexual dysfunction	180	160

^aThe correlation between alprazolam concentration and emergence of side effects was positive for all side effects.

trations over 70 ng/ml were required to have a 50% probability of a major response. Response of the overall phobia score was not significantly related to alprazolam concentrations. It is difficult to explain these findings. They may be related to the fact that only a small number of patients were in the higher alprazolam concentration ranges and the fact that the actual response frequencies varied inconsistently with increasing alprazolam concentrations. Another explanation might be that phobias are not as responsive to alprazolam as are panic attacks and symptoms of anxiety. It also may be that phobias respond best when panic attacks are under the tightest control, i.e., at the higher plasma concentrations. In any case, this finding might explain why the phobias of some patients do not respond to medication, so that the addition of behavioral psychotherapy is indicated.

Alternatively, the phobias may respond, but only at higher alprazolam concentrations, or it might take longer than 6 weeks of drug treatment for phobias to respond. This possibility is consistent with the results using imipramine reported by Mavissakalian et al. (20). In a fixed-dose study, they observed that although panic attacks responded to lower doses and plasma concentrations of imipramine, higher doses and higher concentrations of imipramine were necessary for a good response in terms of reductions in phobic avoidance behavior.

The treatment-emergent symptoms and side effects we observed were those expected from administration of a benzodiazepine. According to logistic regression analysis, they were positively related to steady-state plasma alprazolam concentrations. The only treatment-emergent symptom or side effect that showed a negative correlation with alprazolam plasma concentration was tachycardia. Since tachycardia is a symptom of panic disorder, we would expect it to be better controlled at higher plasma alprazolam concentrations.

A comparison of the steady-state alprazolam concentrations necessary for a 50% probability of response and the 50% probability of the appearance of treatment-emergent side effects can be used to assess the benefit versus side effect ratio. A major response, defined by a reduction in the number of panic attacks, occurred at lower concentrations than those at which

the treatment-emergent symptom of sedation appeared (concentrations for 50% probability were 15 ng/ml for panic response versus 40 ng/ml for sedation). Other CNS side effects were not evident until much higher plasma alprazolam concentrations were obtained, e.g., ataxia at 70 ng/ml and slurred speech at 100 ng/ml. These results must be interpreted in the context of the study, because they are dependent on the rating scales used and the criteria for response classification. They also do not take into account very early treatment-emergent symptoms that may have developed within a few days but subsided as the patient became tolerant to the side effect or the fact that more patients dropped out of the higher alprazolam dose group.

The results of these analyses must not be interpreted as establishing a minimum effective alprazolam concentration or window of effective concentrations for the treatment of panic disorder. Rather, they should be interpreted as demonstrating that there is considerable between-patient variability in alprazolam pharmacokinetics, which explains some, but not all, of the variability in patient response at a given dose. They also offer an understanding that there exist different alprazolam concentrations (and, by inference, doses) which may be necessary to achieve improvement in specific symptoms of the panic syndrome. These findings further support the necessity for careful, individualized alprazolam dose adjustments to achieve the desired treatment response while minimizing undesirable side effects.

A final note of caution: we are not recommending the routine use of benzodiazepine plasma levels for clinical practice. Plasma level determinations of benzodiazepines have not been well standardized and are not readily available in many clinical laboratories. We believe that the use of benzodiazepine plasma levels requires further study in research settings before they can be considered for general practice.

Panic Disorder History in the Families of Patients With Angiographically Normal Coronary Arteries

Matt G. Kushner, Ph.D., Ann Muir Thomas, B.A., Kim M. Bartels, M.A.,
and Bernard D. Beitman, M.D.

Objective: The authors evaluated the diagnostic validity of an interview-based panic disorder diagnosis in cardiology chest pain patients with angiographically normal coronary arteries. **Method:** Patient probands with normal coronary arteries (N=65) were first contacted immediately after their normal angiogram and were given a structured diagnostic interview. On the basis of the results of the interview, probands were grouped as having panic disorder (N=19), panic attacks that did not meet frequency criteria for panic disorder (N=17), or no panic (N=29). At a later time, patient probands were recontacted and given a structured family-history interview that inquired about psychopathology in their first-degree biological relatives (N=544). **Results:** As predicted, panic disorder was significantly more prevalent among the first-degree relatives of probands with normal coronary arteries diagnosed with panic disorder or panic attacks than among the family members of probands with normal coronary arteries without panic (17.4% versus 15.7% versus 4.0%). Family members of probands with panic attacks were significantly more likely to be diagnosed with major depression than were the family members of probands with no panic; however, differences did not reach significance for family members of the panic disorder proband group. Groups did not differ significantly in familial alcoholism. **Conclusions:** These data support the construct validity of an interview-based panic disorder diagnosis among patients with chest pain and normal coronary arteries and suggest that these patients could benefit from treatment for panic disorder. (Am J Psychiatry 1992; 149:1563-1567)

Approximately one-third to one-half of cardiology patients with chest pain and normal coronary arteries meet diagnostic criteria for panic disorder (1, 2); however, several factors call into question the validity of an interview-based panic disorder diagnosis for these patients. Some researchers, for example, have maintained that the chest pain of patients with normal coronary arteries may best be explained by difficult to document cardiovascular abnormalities such as "microvascular angina" (3) or gastrointestinal abnormalities (4). Similarly, although some patients with normal coronary arteries technically meet the criteria for panic disorder, they demonstrate a demographic and symptom profile that is atypical for this diagnosis (5). These findings have led some researchers to suggest that the problems of patients with normal coronary arteries only mirror panic states (6). Thus, although many pa-

tients with normal coronary arteries do meet the criteria for an interview-based panic disorder diagnosis, additional corroborating evidence would appear to be necessary to support the validity of this diagnosis in patients with normal coronary arteries.

Assessment of familial patterns of mental disorder is commonly used to evaluate the validity of putative diagnostic entities (7). It is well documented that the risk for panic disorder in the first-degree relatives of psychiatric patients with panic disorder is two to five times higher than that in control samples (8, 9). Similarly, studies show that 56%–67% of panic disorder patients have at least one first-degree relative with panic disorder (8, 9); again, this is a much higher rate than that found in the general population.

If, as we maintain, panic disorder is a valid diagnosis in patients with chest pain and normal coronary arteries, we would predict a high risk for panic disorder in the first-degree relatives of patients who had normal coronary arteries and this diagnosis, but not in the relatives of other patients with normal coronary arteries. Furthermore, we would expect familial risk for panic disorder among patient probands with normal coronary arteries and a diagnosis of panic disorder to be compa-

rable to that among probands with panic disorder identified in psychiatric samples (i.e., 15%–20%) (8, 9). For cardiology patients with normal coronary arteries who did not have a diagnosis of panic disorder, however, we would expect a familial rate of panic disorder that is comparable to that found in normal control subjects (3%–5%). Secondly, because major depression and alcoholism commonly co-occur with panic disorder (8, 10, 11), we would also expect to find higher rates of these disorders in the relatives of patients with normal coronary arteries and with panic disorder than in the relatives of other patients with normal coronary arteries. The purpose of this study was to test these predictions.

METHOD

Subjects

For this study we attempted to recontact all 94 patients with normal coronary arteries and chest pain who were originally assessed by Beitman et al. (1) approximately 3 years before the present study period. At that time, patients were recruited through a university cardiology clinic immediately after cardiac catheterization. To participate in the original study, patients had to have less than 30% stenosis of all major epicardial arteries and no other cardiac abnormalities that could explain their chest pain. The 65 patients we were able to contact at the follow-up assessment served as proband informants for this study. The final proband group consisted of 20 women and 45 men with a mean age of 56.1 years (SD=11.2 years). Comparisons between participants (N=65) and nonparticipants (N=29), using the original baseline data obtained by Beitman et al. (1), revealed no significant differences on diagnostic variables related to the current study.

Procedure

On the original contact (baseline), Beitman et al. (1) administered the Structured Clinical Interview for DSM-III (SCID) (12) to each patient. On recontact, approximately 3 years later (follow-up), we administered the Family Informant Schedule and Criteria adapted for DSM-III-R (13) to patient probands in order to assess panic disorder, major depression, and alcoholism in all biological, adult, first-degree relatives aged 18 or older, living or deceased, for whom there was adequate information (N=544). The Family Informant Schedule and Criteria is an extension of the Family History Research Diagnostic Criteria developed by Endicott et al. (14). The interview is designed to allow a clinician interviewer to systematically obtain diagnostic information on family members from a proband informant. Rules for coding diagnostic certainty include three categories: definite, probable, and possible. We assigned diagnoses to family members only if they were coded with a definite level of diagnostic certainty.

Using a graded set of techniques for locating study sub-

jects for follow-up, outlined by Russell Noyes (personal communication, March 1989), we attempted to recontact all 94 patients assessed by Beitman et al. (1) during the baseline phase. Sixty-five patients (69%) gave informed consent and served as proband informants. Of the remaining 29 patients, we were unable to locate 19, nine refused to participate, and one was deceased.

On telephone contact, we attempted to set up an appointment for patients to come to our clinic (N=21) to be interviewed; if this was not possible, we attempted to arrange to interview the patient over the telephone (N=44). The interviewer (M.G.K.) was blind to patients' baseline diagnoses. Patients were paid for their participation.

Study Groups and Dependent Variables

For all study analyses, the probands and their first-degree relatives were grouped on the basis of proband baseline SCID diagnosis. Three groups were formed: panic disorder probands, who met all DSM-III criteria for panic disorder; panic attack probands, who experienced panic attacks but not at the frequency required for a diagnosis of panic disorder; and probands with no panic, who did not experience panic attacks. There were two dependent variables of interest in this study: the percentage of first-degree relatives of probands with a study diagnosis (panic disorder, major depression, alcoholism) and the percentage of probands with at least one first-degree relative with a study diagnosis.

RESULTS

Table 1 shows sample characteristics of probands and their first-degree relatives for the three proband groups. Statistical comparisons were accomplished by using analysis of variance for continuously distributed variables and chi-square tests of association for dichotomous variables. The only significant group difference for these variables was the age of study probands. As shown, the probands with panic disorder were significantly younger than probands with no panic; the age of probands with panic attacks was intermediate and not significantly different from the other two proband groups (Tukey's multiple comparison test, $\alpha=0.05$).

Group comparisons on the percentage of probands' first-degree relatives with panic disorder confirmed study predictions. The overall 2 (familial panic disorder diagnosed versus not diagnosed) \times 3 (panic attack versus panic disorder versus no panic disorder proband group membership) chi-square analysis was significant ($\chi^2=18.58$, $df=2$, $N=544$, $p<0.01$). As shown in figure 1, the panic disorder and panic attack proband relative groups did not differ significantly in the percent of members diagnosed with panic disorder (17.4%, $N=29$ of 167 relatives, versus 15.7%, $N=22$ of 140 relatives, respectively). However, both of these relative groups had significantly more members diagnosed with panic disorder than was true for the group made up of the

relatives of the no panic disorder probands (4.0%, $N=11$ of 237 relatives).

Figure 1 also shows proband group differences in the percentage of first-degree relatives diagnosed with major depression. As predicted, the chi-square test confirmed that there was a significant overall effect for group membership ($\chi^2=6.67$, $df=2$, $N=544$, $p<0.05$). Again, as predicted, follow-up tests showed that probands with panic attacks had a higher percentage of first-degree relatives with major depression than did probands with no panic (12.9%, $N=18$, versus 5.5%, $N=13$; figure 1). However, failing to confirm study predictions, probands with panic disorder did not differ significantly from either of the other two proband groups on this variable. Finally, and again failing to confirm study predictions, proband groups were highly similar in the extent to which alcoholism was diagnosed for first-degree relatives (figure 1).

Table 2 shows proband group comparisons of the percentage of probands having at least one first-degree relative with panic disorder, major depression, and alcoholism. As shown, the overall group comparisons for panic disorder were significant. Compared to probands with no panic, significantly more probands with panic disorder and probands with panic attacks had at least one first-degree relative with panic disorder ($\chi^2=8.53$, $df=1$, $N=48$, $p<0.01$; $\chi^2=4.60$, $df=1$, $N=46$, $p<0.05$, respectively). Again, the panic attack and panic disorder

FIGURE 1. DSM-III Diagnoses in First-Degree Relatives of Probands With Chest Pain and Normal Coronary Arteries, by Proband's Panic Attack Status

^aSignificant difference between family members in the panic disorder proband group and those in the no panic proband group ($\chi^2=15.72$, $df=1$, $N=404$, $p<0.01$) and between family members in the panic attack proband group and those in the no panic proband group ($\chi^2=10.70$, $df=1$, $N=377$, $p<0.01$).

^bSignificant difference between family members in the panic attack proband group and those in the no panic proband group ($\chi^2=6.47$, $df=1$, $N=377$, $p<0.01$).

proband groups did not differ significantly on this variable. Thus, the pattern of group differences in the percentage of probands with any panic disordered relatives confirms study predictions and parallels group comparisons of the total percentage of family members diagnosed with panic disorder reported earlier.

Table 2 also shows that, compared to the no panic group, the panic attack group, but not the panic disorder group, had a higher percentage of probands with at least one relative diagnosed with major depression. Table 2 shows that the overall test of this effect approached statistical significance. Exploring the source of this statistical trend further, we again found that only differences between the panic attack and the no panic proband groups were significant ($\chi^2=4.50$, $df=1$, $N=46$, $p<0.05$). Thus, study predictions for this variable were confirmed for the panic attack group but not for the panic disorder proband group. Finally, and again consistent with the negative findings for alcoholism noted earlier, table 2 shows that we found virtually no group difference in the percentage of probands with at least one first-degree relative diagnosed with alcoholism.

DISCUSSION

Study findings support the validity of an interview-based panic disorder diagnosis among patients with

TABLE 2. Probands With Chest Pain and Normal Coronary Arteries Who Had Relatives With DSM-III Diagnoses, by Proband's Panic Attack Status

^aSignificant group effect ($\chi^2=9.76$, $df=2$, $N=65$, $p<0.01$).

^bNearly significant effect ($\chi^2=4.82$, $df=2$, $N=65$, $p<0.10$).

normal coronary arteries. As predicted, the percentage of first-degree relatives diagnosed with panic disorder was significantly higher for probands who themselves received an interview-based diagnosis of panic disorder (17.4%) or panic attack (15.7%) than for the relatives of probands not diagnosed with panic (4.0%). Similarly, we found that 63.2% of the probands with panic disorder and 52.9% of the probands with panic attacks had at least one first-degree relative with a panic disorder diagnosis; however, this was true for only 20.7% of the probands with no panic.

As predicted, these group differences correspond with past studies that compared familial psychopathology in psychiatric samples of panic disorder probands with that of normal control subjects (8, 9). This outcome would not have been expected, however, if panic symptoms in patients with normal coronary arteries only mirrored panic states, as has been suggested by some writers (3, 4, 6). Specifically, we were able to make largely accurate *a priori* predictions both about the direction and magnitude of group differences in familial panic disorder. If a condition other than panic disorder were actually the source of symptoms in patients with panic disorder and patients with panic attacks, there would be no reason to expect the specific group differences that we predicted and found. Therefore, the conclusion that panic disorder identified in patients with normal coronary arteries and their families is the same syndromal entity as panic disorder identified in psychiatric samples would appear to be the most parsimonious interpretation of these findings.

Findings associated with major depression and alcoholism, however, were somewhat less straightforward. Although these findings were partially supportive of study predictions, it is unclear why the family members of probands with panic attacks, but not of probands with panic disorder, showed higher levels of major depression than relatives of probands with no panic. Our failure to find group differences in familial rates of alcoholism may reflect earlier findings suggesting that alcohol-related problems are uncommon among patients with normal coronary arteries and panic disorder (1). In addition, at least one family study reports that while risk for alcoholism is higher among the family members

of agoraphobic patients with panic attacks, this is not the case for the relatives of probands with uncomplicated panic disorder (15). These findings may have implications for those of the present study, as Beitman et al. (1) reported very low levels of agoraphobic avoidance among the patients with panic and normal coronary arteries who were used as subjects in this study.

Several methodological features may limit the generalizability of these findings. First, there can be little question that our use of proband informants to gain diagnostic information about family members (family history method) will yield generally less accurate results than would have the direct interviewing of the family members themselves (family study method). For example, several studies that directly compared these two methods report that the family history method significantly underreports familial psychopathology (16, 17). On the basis of these findings, we could expect that the degree of familial psychopathology in all of our study groups was actually higher than that reported here. Nevertheless, because there is no reason to believe that such a bias should operate differentially among the proband groups, our study conclusions would appear to remain unaffected.

A second issue that may be relevant to the generalizability of these findings is the relative reliability of the telephone interview (68% of the study cohort) versus the personal interview (32% of the cohort) method used in data collection. Although few studies have directly compared these two methods, Colombotos (18) reported that both yielded similar results in a systematic question-and-answer format unrelated to psychiatry. More recently, Paulsen et al. (19) found that diagnoses of panic disorder, depression, and alcohol abuse (the same diagnoses assessed in the current study) could reliably be obtained by using a telephone interview. Using a 12- to 19-month test-retest design, Paulsen et al. reported kappa values ranging from 0.69 to 0.84. Because these values are comparable to, or greater than, those obtained for these diagnoses by using personal interviews (20), it would appear to be likely that the reliability of our data collection methods was adequate.

In addition to the previous interpretational caveats, there could have been an undetected interaction between proband informant diagnosis and response bias to family interview questions. For example, probands who experience panic attacks themselves could be more sensitized to panic symptoms in their relatives and hence more likely to report such symptoms. However, this interpretation appears to be inconsistent with past findings, noted earlier, which show that the family history method tends to underreport rather than overreport familial psychopathology. Beyond this observation, however, it is clear that the appropriate way of ruling out this potential interpretational confound is a replication of this study in which family members are interviewed directly.

Finally, although we do document hypothesized differences in the familial rate of panic disorder for probands with normal coronary arteries who themselves

either do or do not experience panic attacks, this study was not designed to assess the causes of these group differences. That is, although we argue that the pattern of study findings supports the validity of the panic disorder diagnosis among patients with normal coronary arteries, addressing the nature of the mechanisms by which panic disorder is transmitted to family members is well beyond the scope of this study. For example, because panic has been shown to have a genetic component (21), it may have been that the panic attack and panic disorder groups (but not the no panic group) were likely to share a panic-related genetic vulnerability with their biological family members. Alternatively, environmental factors affecting the likelihood of a diagnosis of panic may have been more common in the panic attack and panic disorder groups. Almost assuredly, some combination of these two explanations is more appropriate than is either alone.

In conclusion, these findings corroborate an increasing body of research showing that chest pain for which no medical cause can be firmly identified may be associated with panic disorder (22). Past studies have documented that the symptoms of many cardiology patients with undiagnosed chest pain meet descriptive diagnostic criteria for panic disorder (1, 2). Supporting the view that these are bona fide cases, the current study shows that panic disorder is common in the families of patients with panic and normal coronary arteries but not in the families of other patients with normal coronary arteries. Because effective treatments for panic disorder are available (8), it will be important that patients with normal coronary arteries are routinely evaluated for panic disorder and, when appropriate, referred for treatment.

Phenomenology and Course of Psychiatric Disorders Associated With Combat-Related Posttraumatic Stress Disorder

***Objective:** Studies indicate that chronic combat-related posttraumatic stress disorder (PTSD) is frequently associated with other psychiatric disorders. Questions regarding the nature and interrelationships of these conditions require clarification. The purpose of this study was to address primary and secondary illness relationships by focusing on the specific phenomenology and course of illness onset of PTSD comorbidity. **Method:** In order to minimize confounding factors, only outpatients without recent substance use disorders were included. Sixty subjects who had been exposed to severe combat stress, including veterans of Vietnam and veterans of World War II or Korea, 15 of whom were former prisoners of war, received structured assessments over serial evaluations. **Results:** PTSD was the most prevalent lifetime disorder followed by major depression, panic disorder, generalized anxiety disorder, and phobic disorder or symptoms. Endogenous-appearing features overlapping other clinical populations were common; however, some specific symptom patterns also were suggestive of traumatic influence. Unlike generalized anxiety disorder and past substance use, the mean onset of phobias, major depression, and panic disorder, respectively, occurred later than PTSD. **Conclusions:** These observations suggest that persistent conditions related to PTSD progress toward symptoms that are increasingly autonomous in their pattern of occurrence.*

(Am J Psychiatry 1992; 149:1568-1574)

Among anxiety disorders in *DSM-III-R*, posttraumatic stress disorder (PTSD) is uniquely defined as being linked to external events, specifically, stressors that are overwhelming and extreme. As a syndrome PTSD is defined by symptoms denoting the reexperiencing of trauma, withdrawal, and numbing of responsiveness, and heightened arousal. PTSD has been found to be frequent in veterans of military combat (1, 2) and represents an important concern in providing care to the veteran population. Observations of the frequent occurrence of PTSD with other psychiatric disorders in combat veteran patients, however, challenge the specificity of the relationship of PTSD to overwhelming stress.

There are references in the more traditional psychiatric literature to anxiety and mood-related syndromes

other than PTSD per se as outcomes of trauma (3). One of the first studies to report the association of PTSD with psychiatric comorbidity and to use modern diagnostic categories was by Sierles et al. (4). In that study structured diagnostic assessments were administered to 26 hospitalized veterans, 24 of whom had served in combat in Vietnam. All but one (96%) of the patients met criteria for PTSD, 84% also met criteria for alcoholism or drug dependence, and several patients were noted to have antisocial personality, somatization disorder, and endogenous depression. Seventy-two percent and 64% of the patients were reported to have had past episodes of depression and severe anxiety, respectively. More recently, Davidson et al. (5) reported lifetime diagnoses also assessed by structured interviews of veterans of Vietnam or World War II combat who participated in a medication treatment study of PTSD. Fifty-nine percent of the 44 patients, all diagnosed with PTSD, also met lifetime criteria for major depression, 59% for alcoholism, 47% for generalized anxiety disorder, and 30% for panic disorder. Davidson et al. also reported that alcoholism, PTSD, generalized anxiety, panic, and depression represented, on average, the sequence of illness onset.

While these and other studies have been consistent

with regard to PTSD comorbidity in clinical combat veteran populations, it has been important to confirm the association of PTSD and other psychiatric morbidity with epidemiologic investigations. As part of the Epidemiologic Catchment Area study, Helzer et al. (6) identified 25 cases of PTSD, some of which were combat-related, from a community sample. PTSD was associated with a twofold risk of other psychiatric disorders, with greatest risk being for obsessive-compulsive disorder, dysthymia, and manic-depression. The Vietnam Experience Study of the Centers for Disease Control (2) reported a 66% lifetime prevalence of anxiety or depression and a 39% prevalence of alcohol abuse or dependence among the 15% of war zone veterans found to have PTSD. The more recent National Vietnam Veterans Readjustment Study (1) included 406 male and 170 female veterans who were exposed to high war zone stress in Vietnam. These subjects and other military and civilian control subjects received direct diagnostic interviews and supplemental assessments. From this database Jordan et al. (7) reported a greater prevalence of alcoholism, dysthymia, major depression, obsessive-compulsive disorder, and antisocial personality in the group exposed to high war zone stress. All of these epidemiologic studies relied on the Diagnostic Interview Schedule, a highly structured instrument used by trained lay interviewers, to determine the presence of psychiatric disorders other than PTSD.

Thus, the observation that combat-related PTSD, particularly of a chronic nature, is frequently associated with other psychiatric morbidity is well documented from both clinical and epidemiologic data. There are, however, a number of important questions regarding the nature of this relationship that require further clarification. It has been suggested that alcohol and substance use have a role in precipitating anxiety and mood-related symptoms (8, 9). Their prevalent use in these populations raises the possibility that alcohol and other substances have a role in engendering or sustaining PTSD and comorbid symptoms (as well as use for self-medication). Additional fundamental questions regarding primary and secondary diagnostic relationships are raised by PTSD comorbidity. These include whether PTSD might represent a variation or specific expression of the other frequently associated anxiety or affective disorders or, conversely, whether depression, panic, phobic, or generalized anxiety symptoms develop as associated features or secondary complications of PTSD.

The phenomenology of co-occurring disorders has implications for their relationship to PTSD. A number of features that define PTSD such as emotional numbing, avoidance, and heightened arousal also characterize aspects of depression and phobic and panic disorders. In the definition of PTSD these features are usually linked to trauma-related stimuli. The patterns of occurrence of affective, phobic, and panic symptoms in combat veterans would therefore help to clarify their specificity to PTSD and trauma. In addition, symptom patterns that are considered to be endogenous in na-
